The second case was also that of a young man who had somewhat recently contracted syphilis, but who gave no history of having suffered from secondary symptoms. The duration of his fatal illness was between four and five weeks. For three weeks he complained of frontal headache, unattended with sickness or other important symptoms, at the end of which time he was seized during the night with almost complete left hemiplegia, associated with rigidity of the arm and leg, inability to speak, and well-marked paralysis of the third nerve on the same side. On the next day he had attacks of partial unconsciousness, during which the head and eyes were strongly turned to the left. On the following day he manifested some return of the power of articulation, and was evidently not aphasic. All signs of paralysis of the left third, seventh and ninth nerves had disappeared, and the paralyzed arm and leg had become limp. Three days later the urine, which from the beginning had had to be drawn off with a catheter, had become alkaline and offensive, and there were manifest signs of cystitis; and on that day his temperature reached 103.4°. After this the pulse increased in frequency, the temperature rose irregularly, and on one occasion he had a prolonged rigor; there was a slight return of the paralysis of the left third, seventh, and ninth, and the left arm and leg again got rigid; he passed into a state of coma, and at the time of death the temperature in his axilla had risen to 109.2°. In this case, as in the former, there was reason to suspect the presence of some syphilitic lesion of the brain, and the sudden occurrence of left hemiplegia during its progress, pointed to the direct and sudden involvement of the motor tract in, or issuing from, the right cerebral hemisphere. The partial paralysis of the third nerve on the same side as the hemiplegia seemed to show that the lesion was situated somewhere about the crus cerebri or pons; and that the pons was the actual seat of disease was to some extent confirmed by the attacks of partial unconsciousness, with turning of the head and conjugate deviation of the eyes towards the paralyzed side, which occurred on the second day of his hemiplegia. It will be recollected that deviation of the eyes and head in cases of cerebral disease is towards the lesion and away from the paralyzed side, while it has been observed that, at any rate occasionally, when such deviation shows itself in affections of the pons the direction of the deviation is reversed. The post-mortem examination to some extent confirmed the inferences that might have been, and in a measure were, drawn from the symptoms. There was syphilitic disease of the posterior cerebral and of some of the smaller arteries in the neigh-

borhood; and there was pulpy softening of the right half of the pons. No distinct occlusion of vessels was discovered; but there can be little doubt, I think, that the breaking down of tissue, which was exactly of the same kind as in the former case, and such as one meets with when arteries are obstructed, was the result of obstruction of the small arteries distributed to the softened region.

In this case, as in the other, the cause of the partial paralysis of the third nerve on the same side as the hemiplegia is not clearly explained by the obvious position of the lesion. But the difficulty of articulation which the patient manifested, and the retention of urine with tendency to rapid inflammation of the bladder, had doubtless some relation to the seat of disease. The extremely high temperature which was reached on the approach of death is a noteworthy feature in the case.

The third case was that of a man of middle age who was said to have been temperate and healthy, and never to have had syphilis. His illness began about twelve weeks before death, of which the last seven weeks and a half were spent in hospital. The onset seems to have been a kind of rigor; on which followed persistent headache and giddiness. The first definite sign of brain disease was the occurrence of double vision four days before admission, and the second left hemiplegia, which supervened on the morning of admission. When he came under observation it was found that he had partial paralysis of the right external rectus, and nystagmus of the right eye when trying to look to the right, incomplete left hemiplegia, and unsteadiness of gait. He rapidly got worse, and after four or five days it was observed that his intelligence had become affected, and that he was emotional, that his hemiplegia had become more complete, that the left internal rectus as well as the right external rectus were paralyzed, and that all movements of the eyeballs, excepting that to the left, were attended with nystagmus. He had no optic neuritis. During the following two or three weeks the symptoms underwent little change; but about three or four weeks before his death partial paralysis of the right seventh and ninth was observed for the first time, and he presented also some difficulty of speech and of swallowing. There was no manifest increase of paralysis after this; but he gradually became more and more feeble-minded, and at length comatose. Before death his temperature rose to 103.2° , his pulse to 160, and his respiration to 72 in the minute. In this case there was no evidence of syphilis; but the occurrence of paralysis of the right external rectus with left hemiplegia pointed pretty clearly to mischief about the pons, right crus, or the immediate neighborhood of these parts. And this inference was confirmed when, later, paralysis of the left internal rectus, and still later partial paralysis of the seventh and ninth nerves on the right side, and difficulty of speech and deglutition, supervened. The post-mortem examination revealed softening in about exactly the same situation as in the first case. There was only a little atheroma in the vessels at the base of the brain; there was no sign of syphilitic disease, and no recognized obstruction of vessels. The softening, however, was in the domain of the right posterior cerebral artery, and as there was no trace of present or bygone hemorrhage it seems probable, at least to me, that the softening was the consequence of thrombosis of some of the smaller branches of the artery just named. It is not easy to understand from the post-mortem facts of the case the cause of the paralysis of the left internal rectus or of the right seventh and ninth nerves. It is noticeable that in this case there was nystagmus, and

that in this case, as in the last, there was considerable rise of temperature as death approached.

The last case occurred in the practice of my colleague, Dr. Stone. It was one of thrombotic plugging of the anterior part of the basilar artery, followed by softening of the corresponding region of the pons. The limits of the softening are not defined with precision in the post-mortem record, but the symptoms were those of interruption of the motor tract on the right side, together with much impairment of articulation. It is curious that scarcely any symptoms were present in this case to indicate the exact seat of mischief. It is probable, however, that paralysis of one or other of the cerebral nerves would have appeared had not the patient's life been cut short by his pulmonary complication.

Before proceeding to the detailed account of my cases there are a few points of more or less interest in connection with them, mainly as a group, to which I may briefly refer. 1st. In no case was there any obvious impairment of common sensation or involvement of any of the nerves of special sense. 2nd. In no case did the patient suffer from convulsions. In one, however, there were, for one day, attacks of partial unconsciousness, attended with deviation of the head and eyes towards the paralyzed side. 3rd. There was absence of optic neuritis, at any rate during a considerable period of the patient's illness, in my third case, and I believe the same fact was observed in the second, but the record of it has not been preserved. 4th. The affection of the motor nerves at the base of the brain was different in the different cases, and varied to some extent even in the same case; and, moreover, the paralysis was by no means generally most pronounced in those nerves which, judging from the seat of obvious lesion, might have been expected to be the chief sufferers. Several explanations of this phenomenon suggest themselves. Thus, the primary embarrassment of circulation may have involved a wider area than the subsequent softening, and nerve-nuclei at first implicated may have become reinstated; or, again, when necrosal softening had involved a certain district it may either have extended or, acting as a foreign body, may have excited inflammation in the circumambient parts, and so have brought additional nerve-nuclei within its influence; and, further, it is well known that most of the motor nerves at the base of the brain, and more especially, perhaps, the sixth, are liable to be interfered with either by the effects of basal meningitis, or by direct pressure exerted by a superincumbent tumour or swelling. The cases show, however, that valuable as paralysis of these nerves is as a guide to us in the diagnosis of the seat of intracranial lesions, their indications require to be read with care, and we cannot safely attach specific value to them indiscriminately. It may be added that in one of my cases there was paralysis of the right external rectus, which might have been expected from the seat of lesion, and also of the left internal rectus, of which the cause was not apparent. It seems probable that in this instance there was implication of the centre, which co-ordinates the actions of these muscles.

Secondary Syphilis; Disease of Right Posterior Cerebral Artery and Softening of Right Crus Cerebri, Optic Thalamus, etc.; Left Hemiplegia; Paralysis of Right Ocular Muscles.—F. M. W. B.—, aged thirty-three, an attendant at a lunatic asylum, was admitted on April 16th, 1872. It was stated that he had had primary syphilis in the previous October, and that this had been followed by sore-throat and psoriasis. He had been treated for his complaint, I believe, with iodide of potassium and mercury, and under the influence of treatment his symptoms

had gradually subsided, but not disappeared. In all other respects his health had been good up to three or four weeks before admission. He then complained of headache, chiefly occipital, which was followed in a week or ten days by vomiting, coming on for the most part directly or very shortly after meals. These symptoms have been persistent since their first appearance. He has had no pain in the chest or between the shoulders either after food or at any other time, but his appetite has been bad and his bowels constipated. He has had no cough. On admission he was still complaining of occipital headache; his tongue was thickly coated, but no disease of any important organ could be detected. The heart and lung-sounds were healthy, the urine free from albumen, and with a specific gravity of 1027. The limbs, trunk, and especially the face, presented abundant traces of syphilitic psoriasis.—17th: Has slept badly, but has not been sick; has had much headache. There is no affection of any of the organs of sense, and he is perfectly rational. Tongue very thickly coated, white. Pulse 52; temperature 99°; bowels not open.—18th: Seems better, but has much headache, and slept badly. Temperature 99°.—20th: Has been twice sick since the last visit, has slept badly, and has rambled a little both day and night. Last night he got out of bed and tried to get into one on the opposite side of the ward, and he threw a spoon at the nurse. He speaks quite rationally when answering questions, but does not know where he is, and rambles a little when left to himself. He complains very much of headache, which appears to be general. He can see with both eyes, but complains of muscæ. Both pupils are contracted, but the right is most so, and seems to act less perfectly than the other. Both conjunctivæ are congested, especially the left. The muscles of the eyeballs act normally, but the left upper eyelid seems a little dropped. Tongue less thickly coated than it was; appetite bad; pulse 50. No indications of thoracic mischief or of renal affection.—24th: No material change. He had thirty grains of chloral hydrate last night, slept well, and is very drowsy this morning. Says he feels better, but that his head is painful. Tongue much furred; bowels confined; pulse 54.—25th: Had a tolerably quiet night, but this morning it was noticed that he had paralysis of the left side of the body. Neither himself nor the nurse could give any account of its coming on. He cannot now move arm or leg; but sensation appears to be unimpaired in them, and reflex movements are readily excited. The mouth is drawn to the right, and the tongue deviates slightly to the left. There is no change for the worse in any of his organs of sense. He is fairly sensible, and answers questions pretty readily. Complains of pain across forehead, in back of head, and in neck. Pulse 68.—27th: Has slept pretty well the last night or two. Complains of headache still. Paralysis continues unchanged. Has had no sickness lately, and the bowels have been confined since the 25th, since when he has passed his urine into the bed. Conjunctivæ congested; pupils contracted. Tongue furred. Pulse 56.—29th: No improvement. Is certainly more dull and stupid than he was. The tongue still distinctly deviates to the left. There is no change in the condition of his pupils, but their axes now do not correspond. The left eye seems to move freely and perfectly; but the right moves neither upwards, nor inwards, nor outwards; the only movement which it executes is downwards, with an inclination to the right.—May 1st: Now takes no notice of anything that is said to him. The left upper eyelid droops more than the right; but the muscles of the right eye are paralyzed. The pupils are equal and somewhat con-

tracted. He does not appear to see. Water passed into the bed. Pulse 60.—2nd: Was very quiet all last night, and now takes no notice whatever, however loudly he is addressed. He lies on his back with the eyes closed, and when the lids are raised the right eye is seen to be directed straight forwards, the left pointing downwards and to the left. The former is quite motionless, but the left is occasionally brought into the same position as the right. He does not follow or appear to notice the light of a candle however near it is brought to the eyes, nor does the light affect the pupils, which are as nearly equal as possible, and somewhat dilated. He breathes gently and noiselessly, and occasionally rubs his eyes with his right hand. He has had no convulsive attacks. Pulse 96. The syphilitic eruption has improved since admission, but it is still quite apparent. His death took place next morning.

Autopsy.—There is slight thickening of the membranes at the base of the brain, but no noticeable flattening or congestion of the general surface. The right posterior cerebral artery for about an inch of its length is considerably thickened and slightly translucent, and the channel of the vessel, which is much narrowed, is occluded by a tough, adherent, cylindrical, fibrinous coagulum. All the other vessels are healthy. A tract of softening involves the right crus cerebri, the outer part of the right optic thalamus and internal capsule, and the brain substance to the outer side of the hippocampus major; and patches of disintegration are present in each of these situations. The third nerve of the left side is enlarged. There is a great deal of effusion into the lateral ventricles. All other parts of the brain are healthy. Thoracic and abdominal viscera all healthy. No syphilitic disease of any of these organs.

Acute Softening of Right Half of Pons Varolii; Left Hemiplegia; Partial Paralysis of Left Third Nerve, &c.; Coma and Great Rise of Temperature before Death.—James P—, a gardener, aged twenty-seven, came under my care on Dec. 24th, 1881. Has been of loose habits and has drunk a good deal, and about two years ago had an attack of syphilis. Has had no other illness of importance. For three weeks he has complained of pain in the frontal region, which has become more severe during the last two days, and has been attended with loss of appetite; no sickness. He went to bed on the night of the 23rd fairly well but for his persistent headache. At 5.30 the next morning his brother found him lying on the floor, and thought he was drunk; he was partially insensible, and when he was being replaced in bed the brother noticed that he struggled only with one side. He was admitted into the hospital a few hours afterwards. At that time he was partially unconscious; the pupils were dilated and equal; there was an external squint of the left eye, and ptosis of the left eyelid; the upward movement of this eye also was a little impaired; the mouth appeared to be drawn slightly to the right, and the tongue was protruded markedly to the left; he was unable to speak, but seemed to understand what was said to him, and complained of pain in the frontal region; no difficulty of swallowing; the left arm was flexed at the elbow and lay across the chest; the hand also was closed; the whole limb was rigid and completely paralyzed; the left leg also was rigid, but extended, and he retained slight power over the movement of the toes; the patellar reflex was brisk in both legs, but chiefly in the left; no ankle clonus; plantar reflex almost absent in the left side; left leg colder than the right; no loss or impairment of sensation; thoracic and abdominal viscera healthy. Pulse 90.—25th: Was very restless dur-

ing the night, and to-day is much the same as yesterday; paralytic phenomena remain unchanged; he is unable to speak, but evidently understands what is said to him; the water has to be drawn off; he has had occasional attacks of increased, but still incomplete, unconsciousness, during which the head and both eyes were turned strongly to the left.—26th: Still very restless. He begins to speak, though indistinctly, and is evidently not aphasic. The paralysis of the left third has almost wholly disappeared, and the suspected paralysis of the other muscles of the face is not noticeable. The left arm and leg are fully as powerless as they were, but they are now limp. Superficial and deep reflexes increased on left side. Urine still has to be drawn off; specific gravity 1028, no albumen.—29th: The patient has been very restless; has suffered from much pain in the bladder, and the urine has become offensive and alkaline. The bladder has consequently been washed out. The temperature, which ever since admission has varied between 99° and 100·2°, began to rise on the morning of the 28th, and this morning early reached 103·4°; tongue dry.—31st: The restlessness and severe pain in the vesical region have continued; but the urine, which still has to be drawn off, has ceased to be offensive, and has become slightly acid, and contains no trace of albumen. The temperature rose to 104·9° last night, when he had a rigor of twenty minutes' duration. This afternoon it reached 105·2° without the occurrence of a rigor; tongue dry; no rigidity of limbs; speech as before.—Jan. 2nd, 1882: Still restless and in pain; complains also of pain in the right side of the head and down the left arm; is quite sensible, and occasionally cries out. The limbs are rigid again, and since yesterday there has been slight ptosis of the left eyelid, and protrusion of tongue to left. The condition of the facial muscles is doubtful; tongue dry and brown; much vomiting; obstinate constipation; pulse 116. The temperature on the 1st fell from 103·2° in the early morning to 98·2° at noon; it subsequently rose again, and during the later part of this day and the 2nd varied from 97·8° to 101·4°; a bedsore on left buttock.—3rd: Much quieter, and almost unconscious. Both pupils much dilated, especially left; pulse 132; respiration noisy, 48 in the minute. Tongue very dry; paralytic symptoms unchanged; temperature varying between 100·8° and 103·5°.—4th: When seen this morning he was fast sinking and wholly unconscious. He died at noon. His temperature rapidly rose before death. At 11 it was 106·6°; at 11.30, 107·1°, and at the time of death, 109·2°; half an hour later it was 108·4°.

Autopsy.—Vessels of pia mater injected, but no trace of meningitis, and nothing abnormal as regards the form of the general surface of the brain, or the subarachnoid fluid. The posterior cerebral, and some of the smaller arteries in the neighborhood, were much thickened, yellowish, and opaque, apparently the seat of syphilitic disease. But the other and larger vessels were fairly healthy. There was slight comparative softening of the left temporo-sphenoidal lobe; and the pons, which was somewhat swollen, was soft and semi-fluctuating. On incising this part an irregular patch of broken-down brain substance occupied the greater part of its right half, being separated from the surface, and from the surrounding healthy substance, by a zone of congested and apparently inflamed tissue. The substance of the temporo-sphenoidal lobe appeared fairly healthy. The rest of the brain substance was normal. There was, perhaps, a slight excess of fluid in the ventricles. A few old pleural adhesions. Lungs congested and cedematous below. Larger bronchi full of muco-purulent fluid. Pericardium

and heart healthy. The abdominal viscera presented nothing unusual. Kidneys rather large and pale. No syphilitic affection of any of these organs.

Softening of Right Crus Cerebri and Lenticular Nucleus; Left Hemiplegia; Paralysis of Right External and Left Internal Rectus, and later of Right Facial and Right Hypoglossal Nerves; Nystagmus; Giddiness; Headache; Emotional and Mental Disturbance.—H. T—, a laborer, aged forty-six, came under my care on Dec. 11th, 1879. He has been a temperate and healthy man, and has had no important illness since childhood. Never had syphilis. His illness began early in November with a sense of coldness and shivering, which were not relieved by sitting in front of the fire. The next day he first complained of giddiness, and a feeling as if he were drunk. This giddiness, which continued, was most marked in the morning, and was always relieved by lying down. He further complained of pain at the right side of the head and neck behind, and also across the back of both eyes. He has had no nausea or sickness. On Dec. 7th he began to see double, and on the day of admission he first noticed that his left arm was weak, and his leg dragged. He is a well-nourished man. He is quite sensible, and complains of constant headache, liable to exacerbations of a shooting character, and referred mainly to the back of the right ear and the occiput. He is very unsteady in his gait, and inclined to fall over, but not to one side more than to the other. Can stand with eyes shut when legs are kept apart, but not when feet touch. The movements of both legs are somewhat ataxic; patellar reflex slight. His left leg is somewhat weaker than the right, and the left hand grasps much more feebly than its fellow, and cannot be raised above his head. There is marked weakness of the muscles of the lower part of the face on the left side. The pupils are equal, and respond to light, and there is no very obvious squint. But he complains of seeing double, especially when he looks to the right. In trying to turn his eyes to the right, the right eye lags a little and oscillates. The movements of the left seem quite natural. Optic discs healthy. Tongue protruded straight. No loss of cutaneous sensibility or of control over rectum or bladder. No defect of speech. There are no signs of thoracic or abdominal disease; and the urine is free from albumen and healthy. During the next few days the patient rapidly got worse; he became restless and troublesome, and rambled; he grew emotional, but usually disposed to cry; he lost control over his bladder; his arm became much more enfeebled, and he could do little more than move the fingers; the paralysis of the left side of the face got confirmed, and his tongue was protruded to the left; he still complained of headache, mainly in the right occipital region, and the movements of the eyes became more defective. They were carefully examined on the 16th by Mr. Nettleship, who reported as follows:—"There is diplopia when patient looks to right, but not to left. The movement of the right eye outwards is defective, and efforts to effect it always cause rapid horizontal nystagmus. The left eye cannot be moved inwards beyond the middle line, and the attempt to move it in this direction always causes vertical nystagmus, which is much slower than the nystagmus in the right eye. Both eyes can be freely moved upwards and downwards, but these movements are attended with vertical nystagmus. The only movement of the eyes unattended with nystagmus is that to left. There is paralysis of the left internal rectus, and in a less degree of the right external rectus. There is no optic neuritis." He remained in much the same state for the next two or three weeks; emotional, rambling, and complaining of

pain and sometimes tenderness at vertex; but the paralysis of the left internal rectus diminished somewhat, and on the whole the weakness of the left arm also diminished. The left pupil became larger than the right. On Jan. 6th, it was noticed for the first time that the right side of the face was smoother than the left; that the right eye did not close so perfectly as the other; that the tongue, which had hitherto inclined slightly to the left when put out, now protruded distinctly to the right; that he talked with difficulty, and that he had some difficulty in swallowing. From this time he gradually became more and more feeble-minded and more and more prostrate, without any material change or aggravation in the paralytic symptoms. On Jan. 31st, special note was made of the presence of difficulty of deglutition and of stertorous breathing. On the morning of Feb. 1st, his temperature for the first time exceeded the normal. At this time he became comatose with stertorous breathing, his respiration being 72 in the minute; his pulse was 160; his temperature 102.7° , and his skin was damp. In the course of the day his temperature rose to 103.2° and he died at seven that evening.

Autopsy.—Dura mater and skull healthy; arachnoid and subarachnoid tissue somewhat opaque, with patches of fibroid thickening; slight atheroma of vessels at base. The only lesion discovered in the brain was a patch of softening, with yellow discoloration, which involved the right crus cerebri and the right lenticular nucleus. The surface of the crus looked healthy; and no marks of disease were apparent in the wall of the ventricles. The nerves at the base looked healthy. There was some congestion and lobular pneumonia at the base of the lungs. No other lesion was discovered.

Thrombosis of Basilar Artery; Softening of Anterior Part of Pons; Left Hemiplegia; Death from Bronchitis.—John B—, a laborer, aged thirty, was admitted, under Dr. Stone, on March 16th, 1882. He is said to have been a temperate man, and to have had no previous illness; previously, however, he must have suffered for some time with bronchitic symptoms. He was taken ill five days ago, while at work, with giddiness. He was not sick, and did not fall down; and, indeed, was able to walk home unassisted. After reaching his home he gradually lost power in the left arm and leg, and also his speech, which, however, has improved since. He is a fairly healthy-looking man, but hemiplegic on the left side. There is complete loss of power in the arm; the leg is only partially paralyzed; the mouth is drawn to the right, and the tongue, when protruded, points to the left; pupils equal, contracted, no squint or impairment of vision; speech thick and indistinct; no aphasia; no loss of sensation, either of touch or of special senses. He is quite sensible. He has a frequent dry cough, and some difficulty in breathing. The respiration is 32 in the minute; the breath sounds are attended with sibilant and sonorous rhonchi; chest resonant; heart's sounds and action normal; pulse 100; urine pale, slightly acid, sp. gr. 1015; temperature 99.2° . The paralytic phenomena continued without change, but the bronchitis and dyspnoea increased rapidly; and he died of the effects of bronchitis on the evening of the 22nd. Before death he became very livid and partly unconscious; his respiration rose to 48 in the minute, and his pulse to 144. His temperature never exceeded 101° .

Autopsy.—The basilar artery, just before giving off the the posterior cerebrals, was obstructed for a length of two or three lines by a firm decolorized adherent clot, and the fore part of the pons was softened, and broke up under a stream of water.

No other cerebral disease whatever was discovered. The heart was enlarged on the right side; but all the valves were healthy; and there were no vegetations. The tricuspid, however, was incompetent under the water test. The pleurae were extremely thick and strongly adherent. The lungs were congested, and the bronchial tubes were dilated, and contained muco-purulent fluid. Other organs healthy.

Lectures

ON THE

RELATIONS OF THE TUBERCLE BACILLUS TO PHTHISIS.

By C. THEODORE WILLIAMS, M.A., M.D.,

Fellow of the Royal College of Physicians; Physician to the Hospital for Consumption, Brompton.

LECTURE I.

ITS PATHOLOGICAL ASPECTS.

GENTLEMEN—More than a year has elapsed since Koch's important discovery of the tubercle bacillus, and this period has been occupied by observers of various countries in testing his conclusions in their different aspects, clinical and pathological. We must bear in mind that the great problem which Koch set himself to solve was whether the disease called phthisis was due to the presence in the system, and to its rapid multiplication, of a definite organism, and to no other cause whatever. Villemin, Marcet, Simon, Andrew Clark, and others, finding that by inoculating rodents with tubercular matter they produced tuberculosis in these animals, concluded that phthisis was a specific disease, capable of inoculation, and could only be generated by tubercle. Later on Drs. Sanderson and Wilson Fox succeeded in inducing tuberculosis in guinea-pigs, not only by inoculation with phthisical sputum and tuberculous products, but also with pus, putrid muscle, lardaceous liver, and a number of non-tuberculous materials, and even by inserting setons under the skin, thus overthrowing, for a time at any rate, the doctrine of the specific character of tubercle production. An important point to bear in mind with regard to these last-mentioned experiments is that the experimenters never succeeded in producing tubercle traumatically if the influence of the external air was entirely withdrawn, or if the setons were steeped in carbolic acid. These experiments were repeated by Drs. Waldenburg, Cohnheim, and Fraenkel, who at first apparently arrived at corresponding results, but afterwards were led to change their opinion, as will be seen later on. Schottelins, of Würzburg, produced granular pulmonary tuberculosis in dogs, by making them respire air charged with pulverized phthisical sputum, but he produced similar results with air charged with the expectoration of bronchitis, with Limburg cheese and with vermillion. Klebs, firmly convinced of the specific nature of tubercle, had described an actively moving organism as its cause. Schüller and Toussaint had pictured a spherical micrococcus in connection with the disease. Anfrecht had found more than one form of organism, and thus paved the way for the next step, which was the discovery of Koch. Koch having by means of certain aniline dyes detected the bacillus tuberculosis, succeeded through a series of ingenious cultivations in procuring it pure and simple. He first took tubercle, and after washing it with a solution of corrosive subli-

mate, removed the outer layers and separated a portion into which he might fairly expect that no bacteria of putrefaction had penetrated. This he spread over a nutrient soil consisting of the blood plasma of the ox, which had been previously sterilized by boiling in a test tube. The coagulum of this, with the tubercle added, was introduced into a test-tube with a cotton-wool plug and kept in an oven at a temperature of 37° to 38° C. (98.6° to 100.4° F.) Nothing appeared during the period of incubation of the ordinary bacteria of putrefaction, but at the end of ten days there were seen on the dry surface of the coagulum a number of very small points or dry-looking scales, surrounding the pieces of tubercle spread out in circuits more or less wide according to the distribution of the tubercle fragments. After a few weeks' more exposure these crusts ceased to enlarge, and were then transferred to a fresh test tube containing blood plasma similarly prepared. After another interval of ten days the scales appeared, became confluent, covering more or less of the surface of the coagulum as the seed was scattered, and so from test tube to test tube the experiment was carried out under the most rigorous antiseptic conditions as many as a dozen times and for a period extending over 150 days. With the results of these culture experiments 200 rabbits and guinea-pigs were inoculated, the places selected being under the skin, the peritoneal cavity, or the anterior chamber of the eye. With one exception all these animals acquired tuberculosis of the lungs, liver, spleen, and other organs, the tubercles having the structure of true tubercle and including giant cells, which latter were found to contain bacilli. Such being Koch's results, how are we to account for the production of tubercle by non-specific inoculation, such as Schottelins and others performed? Klebs suggested that they might be ascribed to infection, as the experiments were performed in laboratories at Berlin in the presence either of animals already tuberculous, or where tuberculous materials might remain from previous investigations. Cohnheim and Fraenkel, to test this, repeated their experiments with non-tuberculous materials on similar rodents, Cohnheim in the laboratories of Kiel and Breslau, and Fraenkel in his own home, and with absolutely negative results in both cases, thus demonstrating that the septic atmosphere, and not the simple irritation, was the cause of the tuberculosis. Cohnheim held, previous to Koch's discovery, that the best test of tubercle was its inoculability, and that it was conveyed by specific organisms to the lungs, and affected thus both pleura and bronchial glands. Mr. Watson Cheyne¹ confirms Klebs' suspicions by a series of recent experiments on rodents, which he states he performed under the best hygienic conditions, with complete isolation of the animals from each other, and thorough disinfection by heat of the instruments used. In six cases setons of various kinds were introduced either subcutaneously or into the anterior chamber of the eye. In ten vaccine lymph was used, in three pyæmic pus was injected either into the eye or under the skin, or into the abdomen; in six, various materials, such as cork, hardened tubercle which had been soaked for three months in alcohol, or worsted, were introduced into the abdominal cavity. In none of these rodents did tuberculosis result. Mr. Cheyne also made experiments with cultivations of bacilli obtained from Dr. Koch. He inoculated twelve animals with these organisms, chiefly into the anterior chamber of the eye; all of them became tuberculous, and more rapidly than after the inoculation with tubercular tissue. The tubercle obtained

from these cases was again inoculated and shown to be infective, causing tuberculosis in other animals and containing the tubercle bacilli, which were found to be most numerous when obtained from bovine tuberculosis, and least so when taken from human tubercle. It appears impossible to resist the force of these demonstrations, and we are compelled to admit that there is a specific element in tubercle, the presence or absence of which determines the success or failure of the inoculation. This element is apparently the tubercle bacillus, but we must not exclude the possibility of other organisms playing a part in the process of tuberculosis. The publication of Koch's paper was followed by a search after the bacillus by a large number of observers in various countries. The sputum of phthisis was tried for the bacillus by Balmer, Fraenkel, D'Espines, Heron, Heneage Gibbes, West, Dreschfeld, Whipham, and myself among others, and our conclusions confirmed those of Koch as to its almost invariable presence in phthisis and its absence from the sputum of other chest diseases. To the particulars of my own researches I will allude more fully presently. The bacillus has also been detected in the purulent effusion of a knee-joint, in tuberculous ulcers of the intestine, and in tuberculous kidney, and it is stated to have been discovered in the lymphatics of the lung, and doubtless in time it will be discovered in other organs.

Few institutions could be more interested in this discovery than this hospital, which is for the most part devoted to the investigation and treatment of consumption, and in which any aids to diagnosis and prevention are heartily welcomed. The subject was soon taken up, and our labors were directed towards testing (1) the sputum, (2) the blood of the patients, and (3) the air of the wards. With regard to tests, Koch's original plan did not give us very successful results; Ehrlich's answered better, and with Weigert's additions seems excellent, but Heneage Gibbes' was early adopted on account of its simplicity and speed, and a fresh mass of cases were thus examined, the bacilli being stained with magenta-aniline, and the ground substance with chrysoidin or methylene blue. Lately, however, I have adopted a modification somewhat resembling Rindfleisch and Chill's,² which still further simplifies and shortens the process. The cover-glass with the dried sputum thereon is floated in a few drops of magenta aniline in a watch-glass, and heated over a flame till vapor is seen to rise from the surface. The watch-glass is then removed and allowed to cool for two or three minutes, the cover-glass is afterwards treated successively with nitric acid (1 in 4), with distilled water and a weak solution of alcohol. It is dried and mounted in Canada balsam, the whole process not exceeding eight minutes. When, however, I am doubtful of a result, I test a second specimen, this time allowing the cover-glass to remain in magenta-aniline for a long period—say, of twenty-four hours—and subsequently compare the two; but I generally find that the first method is sufficiently accurate. This process has answered well for detecting the bacillus tuberculosis quickly in sputum; but Gibbes' solution does sometimes color putrefactive bacilli, and if the second solution be not used, we have to be careful, though the form and size of these latter differ entirely from those of the tubercle bacilli. Another difficulty is that the red staining of such preparations often fades, owing, Dr. Gibbes tells me, to the fact of heat being used; but I have also noted the fading in several slides where heat was not used. Dr. Gibbes' new process has the advantage of

¹ Practitioner, April, 1883.

² Deutsche Medicinische Wochenschrift, No. 2, 1883.

getting rid of the nitric acid, of rapidly staining the tubercle bacilli, the putrefactive bacilli, and various micrococci blue, thus demonstrating most of the organisms present in the sputum of phthisis. Dr. Gibbs showed me the process, and kindly furnished me with some of the solution. He has noted one form of micrococcus frequently present in addition to the tubercle bacillus. I have not tried this process largely; but as yet it has not proved as successful in my hands as the former ones, partly owing to the density of the fluid, and partly to some of the tubercle bacilli being colored a sort of neutral tint instead of red. The Weigert-Ehrlich solution (saturated watery solution of aniline 100 cubic centimetres, saturated alcoholic solution of fuchsin or magenta ten cubic centimetres) is an excellent stain for sputum sections. I have sometimes substituted it for Gibbs' because of its less intense color and greater fluidity, and obtained very good results. Under the microscope you will find sputum of consumptive patients containing bacilli stained by all these various processes, as well as some admirable sections of tubercle of the lungs and trachea, and cavity scrapings tinted by the Weigert-Ehrlich process, kindly exhibited by our pathologist, Dr. Percy Kidd. (Specimens exhibited.) One of these last shows the massing of the bacilli on the ulcerated mucous surface of the trachea in a remarkable manner. Some account of the general results of the examination of the sputum were given in *THE LANCET* a few months since; but since that time we have added considerably to our numbers, which amount now to about 200, many of which have been made the subject of separate clinical study, as will be seen later on. Twenty-three patients were examples of lung affections other than phthisis—viz., asthma, emphysema, bronchitis, pleurisy, chronic pneumonia, pulmonary congestion, bronchiectasis, and empyema. In no one instance of these did the sputum contain bacilli. On the other hand, of the 200 cases of phthisis, which included acute and chronic forms in all stages of the disease, in all but three, bacilli were found. The blood of several acute cases of phthisis was next examined, but here we entirely failed to detect bacilli, though, judging by the height of the fever and the evident infection of the system, we were quite prepared to find them.

The next point of investigation was the air of the hospital. As a convenient way of testing this, I selected one of the ventilation shafts in which the flues of several wards converge, and in which extraction takes place at the rate of 300 to 400 feet a minute. In this current I suspended glass plates smeared with glycerine for a period of five days. The plates were then washed with distilled water, the fluid mixed with a little mucilage and evaporated down to half, and the residue tested for bacilli, which were found in fair abundance. I may mention that the wards from which this air came contained a small proportion of chest cases other than phthisis, though the great majority of the patients were phthisical. As a further experiment, by Dr. Green's suggestion, I had a number of non-phthisical patients placed in a ward recently cleaned out and whitewashed, and I suspended similar glass plates in the extracting flues, and here there were no bacilli found. Another ward was filled with consumptive patients, some in an advanced stage, and the air extracted from this ward similarly tested. A slide containing dust from this ward flue is placed under one of the microscopes, and you will see a few bacilli in the field, not in abundance, or of great length, as we see in the sputum, but few and rather short, but still definite. This plate was exposed for fourteen days in the flue, and is conclusive in its

results. Mr. Percex, one of the clinical assistants, at my request, examined the blood expectorated in two cases of hæmoptysis under the care of Dr. Tatham, and in each found bacilli.

Before giving in detail the clinical cases bearing on the bacillus, it would be well to advert to what is at present known of the part it plays in the pathology of phthisis. The able report of Mr. Watson Cheyne has shown that the success in inoculating animals, whether rodents or carnivora, depends on the bacilli contained in the material employed, the certainty of the production of tuberculosis by inoculation of tuberculous material, and the rapidity of its occurrence, being in a direct ratio to the number of bacilli present in the inoculating material, whether this is caseous gland, bovine tubercle, phthisical sputum, or bacilli growing free in serum, the two latter being by far the most efficacious agents. All these experiments, however, produce general tuberculosis, and the only disease that is exactly akin to this induced form is acute tuberculosis in man, and Mr. Cheyne considers these to be identical. But when we come to pulmonary phthisis, chronic or acute—that is, the disease beginning in the lungs—we are met by some difficulties with regard to the bacillus, for while bacilli are found in great abundance on the linings of cavities and in caseous masses, they are not so commonly detected in other parts of the lung structure—in fibrosis, for instance. Dr. Samuel West regards their presence in the sputum as a proof of excavation, and their numbers as easy means of estimating the rate at which this process is taking place in the lung. Mr. Cheyne, as an explanation of the comparative rarity of the bacillus in sections of tubercle, states that two distinct structures have been described under this title:—

1. Nodules of lymphatic tissue in close proximity to the vessels and bronchi. These contain no bacilli.
2. Nodules largely made up of epithelioid cells and containing bacilli.

The first he considers the result of irritation on the lymphatic tissue of the lung, the second being the seat of infection. These last consist of epithelioid and giant cells surrounded by inflammatory (lymphatic) tissue, the bacilli being found in the epithelium, and largely in the giant cells. When caseation takes place in the centre of the tubercle, the bacilli are to be found in the caseous mass, but are best seen in the still living cells. One of the chief points which Mr. Cheyne lays stress on is that the habitat of the bacillus is the aveolar epithelium and the products of its proliferation—to wit, the single nucleated and the multi-nucleated or giant cell. It is here that the bacillus settles and causes multiplication of the cells, even escaping from the circulation into the lymphatics to reach this favorite haunt. In ordinary phthisis the bacilli are supposed to reach the lung by inhalation, and to develop in the aveolar epithelium, causing its proliferation by irritation. The aveolus becomes stuffed with cells; giant ones being formed, if the process be a slow one; if quick, caseation taking place early. Infection of neighboring aveoli proceeds partly by continuity, partly by the coughing up and re-inhalation of bacilli into other parts of the lung. The further progress depends on the rate of growth of the bacilli, and on the fitness of the soil for their development. If they multiply quickly, caseous pneumonia and rapid excavation of the lung will ensue; but if slowly, the irritation of their presence, and of the resulting caseation, may cause thickening of the aveolar wall with inflammatory tissue, and a fibrous barrier be presented to further infection, and thus the evil doing of the bacilli may be localized. This is what takes place most markedly in fibroid phthisis, where the bacilli are very rare. On the

other hand, if the barrier be feeble and the lungs become largely involved, the walls of the pulmonary veins having tubercular masses in them, as Weigert and Mügge have shown, the bacilli enter the circulation and acute tuberculosis is the result. Weigert has also found that the innominate veins may be affected from the neighboring bronchial glands, and Koch had a case, cited by Mr. Cheyne, in which the wall of an artery was involved in acute miliary tuberculosis, through spread of disease from a bronchial gland.

It must be admitted that this view of the pathology of phthisis is lucid, and, as far as the results of experiments on animals can be cited to prove the analogy with human disease, it is apparently impregnable. It explains several of the histological features of tubercle, the epithelial accumulations within the alveoli, the formation of giant cells, the exudation of fibrin and leucocytes, all these being the result of irritation from the bacilli; but it does not equally well explain the small-celled or lymphoid tissue commencing in the alveolar walls, and by its rapid growth, according to Dr. Wilson Fox, leading to obliteration of the capillaries and necrobiosis of the parts involved. The inflammatory tissue described by Mr. Cheyne differs from this in the absence of the delicate reticulum noted by Dr. Sanderson, the existence of which Mr. Cheyne appears to doubt, and instead of leading to destruction by caseation appears to resemble the part played by the interlobular growth in limiting the spread of the changes, caseation taking place only in the epithelioid elements, and not in the alveolar wall; this latter, however, eventually disappearing by pressure, and its destruction giving rise to the formation of cavities. The limited portion of the lungs attacked in early phthisis is also accounted for; for here the bacilli enter only a few alveoli; and the fact of the apices being first attacked may depend, as Dr. Green shows, on the presence of inflammatory exudations, the result of more or less injury to the pulmonary vessels through stagnation of the blood. This arises from the imperfect exercise of the upper lobes. The spread of tubercle round cavities or centres of caseation would be assigned to the bacilli entering the lymphatics of the district, and the infection of the opposite lung might arise through the lymphatics or the blood vessels from inhalation of some of the sputum. For infection of other organs we must take it for granted that the pulmonary vessels are involved, and in this case we may have tuberculosis of the membranes of the brain, spinal cord, abdomen, as well as the liver, kidneys, etc. Infection might also take place through the lymphatic system of the bronchial glands. On this theory we may explain the limitation to the lungs of acute phthisis (caseous pneumonia), acute tuberculo-pneumonic phthisis, catarrhal phthisis, and the spread through the whole body of acute tuberculosis. The predominance of the growth of the inflammatory tissue would give us some key to the phenomena of fibroid phthisis, but to my mind it fails to explain the thoroughly constitutional features of scrofulous phthisis, nor do I quite see how the causation of the hæmorrhagic variety, characterized by small consolidations and large hæmoptyses, is brought about. Laryngeal phthisis is also a difficulty; for why, as Dr. Percy Kidd suggests, with the bacilli-laden sputum passing continually over the larynx, do we not get ulceration in all cavity cases? Another grave objection lies in the fact, that though the bacilli have been found abundantly in the walls of cavities, they have seldom been detected, and only in small numbers, in sections of human phthisical lung tissue. Even Mr. Cheyne admits this; but it may be due to so much of the epithelial element, the

habitat of the bacilli, disappearing before death, either by the invasion of fibrosis or by caseation and expectoration. The bacilli have been detected in tubercle of the peritoneum, and in miliary tubercle of the lung, but always in small numbers. There is, therefore, a wide field for further pathological investigation on these points, but seeing how many difficulties in the way of accepting the bacillus theory have already been overcome, it must be admitted that there is strong probability, in favor of these also being explained by the aid of improved methods of investigation. Another element which we must not overlook in the consideration of this matter, is the question of a fitting soil, and assuredly all the advocates of the bacillus fall back largely on this, for in many cases we can hardly escape the conclusion that bacilli enter the respiratory tract, and even the alveoli, and do not give rise to phthisis, which can only be explained on the ground that the constitution of the individual rendered the epithelium unfit for their reception; and in truth, if we are to accept the bacillus theory at all, we must suppose that the various and well-known predisposing causes of phthisis, such as dampness of soil, bad ventilation, bad confinements, and other debilitating conditions, must act by preparing a fit soil for the bacillus either by bringing about low inflammatory conditions, which tend to cellular products, or by weakening the resisting powers of the constitution. The recognition of one exciting cause instead of many will tend to simplify the etiology of phthisis, and will lead us, it is to be hoped, not only to direct remedial measures against this latter, but equally, and perhaps more effectually, against the predisposing causes.

The tubercle bacillus is generally described as varying in length from 1-3,000 of an inch to 1-12,000, and having a breadth one-fifth of its length. As regards breadth, it is generally uniform, though I have noted some bacilli double the thickness of others, the thickest ones being invariably beaded and ready to divide. I have, therefore, concluded that these are the older rods, and that the others are of younger growth. As regards length, I find them vary greatly. Some are only twice as long as they are broad, others extend over a twelfth of the diameter of the microscopic field. In form most are straight, with somewhat rounded extremities. The bacilli are not always straight, but often have a curve, sometimes forming a portion of the arc of a circle. With reference to the varying thickness above mentioned, I am aware that this might be due to two bacilli lying on each other, as is often the case; but this can be easily detected by adjusting the focus to different parts of them. Bacilli are found singly or in groups. In the latter case they appear like bundles of sticks, numbering three, four, five—a very common position is two bacilli touching at one end, at an angle of 45°. The grouping of the bacilli generally means mischief, as it is rare to find a number of groups without distinctly advancing disease being present. Bacilli appear to multiply by division, and not uncommonly we see one long straight rod, and parallel with it a second one which is evidently in process of division—i.e., with slight spaces separating three or four segments, all lying in the same line. Often we see a third bacillus in the vicinity, still more broken up into numerous segments, these being separated by wider intervals, but the original connection being still widened by their distribution along the same line. Even under a low power they frequently present a beaded appearance, clear spots alternating with dark germ-like bodies, the beadings varying in number according to the length of the rod. As a rule five or six

are seen, sometimes a larger number, in long rods about to divide. My experience is that the beaded rods may break up into single beads, the bright spore-like bodies of Dr. S. West, which afterwards develop into fresh bacilli, and I have not always been able to recognize the surrounding membrane which Mr. Cheyne describes. In sputum containing bacilli, after being kept in a moderately warm room for ten days, I have noticed a decided increase in the number of bacilli; and when one reflects on the conditions of the air-passages, the combination of warmth and moisture always present, we can understand how multiplication and growth proceed, not only in the alveoli, but in advanced cases, probably also in the larger bronchi, where, owing to the difficulty of expectoration, large accumulations of sputum take place.

Diagnosis.—It is probable that the discovery of the bacillus will assist us more in diagnosing phthisis from other lung affections than in the treatment of the disease. Where it is most useful is in separating clearly cases of chronic pneumonia and those of dilatation of the bronchi from phthisis. We often see an instance of chronic pneumonia with extensive consolidation and well-marked crepitation at the apices of one or both lungs. The history is somewhat obscure, and often, especially if hæmoptysis be present, points to phthisis, and the physical signs rather incline us to hold that softening is taking place in an old consolidated lung. The expectoration if carefully examined and found to contain no bacilli at once settles the point. A good instance of this was a coachman, aged forty-six, whom I saw in consultation with Mr. Tweed in February, 1883. He had been a hard drinker, and had had pneumonia three years previously. A week before a fresh attack had come on, with high temperature and quick pulse. The cough was incessant, the expectoration partly frothy and partly purulent. Crepitation was audible over both lungs, and some dullness at the bases, but cavernous sounds were heard above the right clavicle, which made us both suspect that a cavity had formed in the old consolidated lung, and that the case might have become one of phthisis. Examination of the sputum, which was made more than once, failed to detect any bacilli, and we accordingly came to the conclusion that the case was one of pneumonia, in which previous attacks had given rise to dilatation of the bronchus. It must be borne in mind that had the case been one of phthisis, the bacilli would not only have been present, but in great abundance, as they usually are in cavities when a large discharge is taking place. Another instance was a gentleman, aged forty-six, whom I saw in February of this year. He had pleurisy several years ago, and for four or five years had suffered from cough and expectoration, with slight hæmoptysis. The pulse and temperature were normal. The physical signs showed crepitation over the whole right side, with some spots of coarser crepitation in the first interspace and between the fifth and sixth rib. Dullness extended over the lower half of the right front chest. He complained of great dyspnoea on exertion. Under treatment the cough moderated, but the expectoration remained yellow; there was no wasting, night sweats, or fever. Examination of the sputum showed abundant bacilli, which gradually disappeared as the symptoms diminished. Another class of cases, which are very difficult to diagnose are those of dilatation of the bronchi, following on chronic pneumonia or bronchitis. When the dilatation of the tubes occurs in the lower lobes, the physical signs and the convulsive character of the cough, as well as the factor of the expectoration, render diagnosis easy, but when the bronchiectases are

found scattered over the upper portions of the lungs, as well as in the lower, and when they give rise to cavernous breathing in the first and second interspaces, the diagnosis often becomes exceedingly difficult, and depends chiefly on very careful mapping out of the area of cavernous sounds, such as I have shown elsewhere². In such cases examination of the sputum removes all doubt. The following is a good instance:—

Hannah I—, aged twenty-four, servant, was admitted March 3rd, 1883. Her father died of phthisis; one sister suffers from some chest affection. She had typhoid fever fourteen years ago, followed by scarlet fever, and has been subject to cough ever since; six years ago she had disease of the hip-joint, and become an in-patient of the London Hospital; three years ago she had hæmoptysis (one pint), and the cough has been worse ever since; she has had night sweats for twelve months, and shortness of breath lately; she has lost flesh for six months; her voice disappeared for the whole of one winter two years ago. At present her cough is incessant, and somewhat hard in character. Expectoration yellow, two to three ounces. The patient complains of pain in the left chest; tongue clean; bowels relaxed; pulse 116; respiration 16; temperature 99°. Catamenia absent seven months; aspect cachectic; weight 7 st. 13½ lb. Physical signs: On the left side dullness, crepitation to the fifth rib, posteriorly crepitation over the whole side.—15th: Her cough more troublesome; expectoration one ounce daily; her voice has disappeared; crepitation audible under the right clavicle. No bacilli could be found in the sputum.—30th: Her cough worse; crepitation less on the left side; no bacilli in sputum.—April 7th: Her cough increasing; expectoration more abundant, purulent, and decidedly fetid. The patient has herpes labialis. Dr. Kidd examined the larynx and found the vocal cords healthy, but adduction imperfect. No bacilli in sputum.—19th: Her cough somewhat better, but still bad at night, and is remarkably convulsive; expectoration has a sulphurous odor. Physical signs: On the left side the crepitation has much diminished, but tubular sounds are audible over a small area below the scapula. The sputum has been again examined, with negative result. The history of this case, especially the facts of the cough and expectoration following hip disease, pointed towards phthisis. The convulsive character of the cough and the hysterical aphonia raised doubts in my mind, which the examination of the sputum strengthened, and which were entirely confirmed by the latter becoming fetid.

Another group of cases in which the diagnosis will be materially assisted by the bacillus, is where the catarrhal symptoms mask the consumptive ones; and here specially, when there is no pyrexia present, the detection of the consolidation is often difficult. A good example of this will be later given in Lecture II., where the history pointed to asthma, though the phthisical signs made us suspect tubercular disease at one apex, which the detection of bacilli confirmed.

I had a remarkable exemplification, the other day, of the use of this test in a case of chronic empyema, where in spite of free drainage and absence of all fever, the temperature chart pointed to some form of septicæmia, and I suspected at once that there was absorption of the matter and commencing tuberculosis of the opposite lung. Examination of the sputum showed a fair number of bacilli, and about the same time, fine crepitation was detected in the first interspace on the right side, the empyema being on the left.

² British Medical Journal, 1882.

Cases of laryngeal phthisis at an early stage present occasional difficulties of diagnosis, partly from the mucous membrane of the larynx being swollen, and not presenting distinctive ulceration, and partly because, respiration being a painful act, the patient does not breathe sufficiently deeply to give auscultation a fair chance. Here, again the examination of the sputum helps us considerably. A gentleman, aged thirty-five, who is at present under my care with a decidedly phthisical history, came in February with loss of voice, which he stated was only an occasional symptom, with cough and abundant expectoration, loss of flesh, and night sweats. Examination of the chest showed obscure breathing in almost every part with fine crepitation under the right clavicle. The larynx presented a red and somewhat tumid mucous membrane, and at a later date the crepitation above mentioned passed away. The sputum was examined and found to contain abundant bacilli. About a month later crepitation was detected at the left apex, and a cavity rapidly formed, the larynx now exhibiting the characteristic features of tubercular ulceration. In this case it is true that the general evidence pointed towards phthisis, but the paucity of the physical signs and the character of the patient made me strongly suspect syphilis, which the detection of the bacilli and the after-history of the case negatived. However valuable this test is in the above classes of cases, we must never allow it to interfere with most careful physical examination of the chest, as, after all, the presence of bacilli cannot define the locality, or even the extent, of the diseased area, but can only indicate the existence of the morbid process.

Original Papers.

REMARKS ON ONE FORM OF LAWN TENNIS KNEE.

By C. MANSSELL MOULLIN, F.R.C.S.,
Assistant-Surgeon to the London Hospital.

ALL amusements have their drawbacks, inherent and unavoidable. Concerning football, it is scarcely necessary to speak, perhaps too much has been said already; rowing, especially in scratch races, the same; riding, not to include falling off, has its riders' sprain; lawn tennis its wrist, and now I must add its knee. As in all the rest, so in this; it is not the practiced player who comes to grief; most often it is he who has enjoyed a reputation in years gone by. Those who contend in university races, for which men are selected and trained with the greatest care, rarely meet with harm; college fours and scratch races of like character, perhaps only for a very short distance, for which all trained and untrained alike enter, too often work the ill for which the others get the blame. Thus it may be that, just now, at this time of year when tennis is being extensively played in suburban gardens, when the city clerk and the professional man engaged all day and for days past through the winter in some sedentary occupation suddenly indulge in an afternoon's amusement, tennis knees come prominently before our notice. At least, to say nothing of old friends whose appearance one expects regularly at the commencement of each season, I have quite recently seen several all of the same character. They do not understand how it could have happened; "it was only a twist, you know; just like that you—," and the sentence ends unfinished, while the patient sits down abruptly on the nearest chair

with a look on his face that may express anything, but not comfort.

Now there are many kinds of ill that may befall a knee as the result of tennis, but it is only with one of these that I intend to deal at present. Loose cartilages attributed to it as a cause are certainly not infrequent; nor is that condition of profusely fringed synovial membrane that often gives rise to the same sort of symptoms, and keeps working within a most vicious circle by being at once the result of past attacks and a sufficient cause for future ones; irregular sprains of all or any of the ligaments in and round the joint, and even complete displacement of a semilunar cartilage, have been recorded; while more rarely found are instances of that peculiar form of internal derangement, causing locking of the joint, described by Hey and Knott.

Mine is not quite any of these, but rather a strain of that particular portion of the internal semilunar cartilage which finds its insertion by means of a strong band of ligamentous fibres on the outer side of the inner tuberosity of the tibia, just in front of the spine, and it is always produced or capable of being produced by the same definite and characteristic movement. The player is standing with his knee slightly flexed, resting his weight on one foot—say the right—the left one touching the ground behind with the toes; suddenly he makes a twist round, bringing the left leg to the front, and while doing so either reaches as far forward as he can, or more frequently attempts to spring from the right foot. The immediate result is a fearful pain in the right knee, often causing him to fall, while at the same time his face becomes pale, and the feeling of sickness so characteristic of a sprain comes over him. The knee itself rapidly fills with fluid. In the majority of cases nothing else abnormal can be found, and though the effusion under proper treatment is readily absorbed, there is left an indefinite sensation of weakness and a tendency to refill, not only when the same movement or anything approaching it is repeated, but under any condition of slight over-exertion. There is no locking of the joint at any time, and in this it differs from both the forms of internal derangement; flexion and extension are only limited by the amount of the effusion and by the pain always felt at the attempt, and there is only one tender spot on a level with the head of the tibia, just on the inner side of the ligamentum patellæ. Sometimes one hears that immediately after the accident there was just at this spot a slight projection, which disappeared at once. One of my patients was quite clear as to this, but I have never seen it myself. Later on, after several attacks, the knee loses its natural shape, and assumes the well-known appearance always left by repeated attacks of synovitis, with wash-leather creaking and the rustle of synovial fringes well marked.

There is only, I believe, one way in which it is possible to explain this accident. The player's right foot is fixed by his weight and by the structure of his tennis soles, and with the foot the tibia, there being of course no rotation permissible at the ankle-joint, so that at the very instant that vigorous extension is being made at the knee-joint the whole momentum of the body, as it is twisted round with the impetus of a sudden spring, is communicated to the lower extremity, which is violently rotated round a vertical axis passing through the inner side of the external condyle of the femur, and corresponding in this position with the plane of the plumb line drawn from the centre of gravity. Thus the two condyles are carried on the tibia, the internal as far forward as the ligaments will allow it, the external to a much less degree backward.

Now this rapid and vigorous movement of the condyles on the tibia is exactly the opposite of that which takes place in normal extension of the limb. There are two kinds of rotatory movement possible between the femur and the tibia. The first is one of pronation and supination in the semi-flexed position of the limb round an axis passing through the tibial spine, and permitted by the relaxation of the anterior crucial ligament in this position; in this the internal condyle remains nearly fixed, the chief movement taking place on the outer side owing in great measure to the mobility of the external semilunar cartilage. The other is a movement of true rotation round a vertical axis running through the external condyle, in virtue of which, when extension takes place, this remains nearly stationary; while, on the other side, the internal tuberosity of the tibia is rotated outwards, carrying with it out of the way the internal semilunar cartilage. The anterior crucial ligament has very little to do with checking this movement, which is mainly controlled by the obliquity of the internal lateral ligament.

In the accident that I have described, at the very instant that rapid and complete extension is made, instead of the inner side of the tibia being rotated outwards as it should be, it is the inner condyle of the femur that is carried in this direction (or the inner tuberosity of the tibia inwards) so far as the posterior crucial ligament and the posterior ligament of the joint will allow it, for the lateral ligaments have no influence, the external being too near the axis, the internal sloping downwards and forwards. As a consequence of this, the anterior portion of the internal semilunar cartilage, which ought in extension to be carried forwards out of the way, is caught by the prominent internal condyle, and, owing to its wedge shape, driven violently to the front. So far as the cartilage itself is concerned, this is of small moment, as it appears to be a tissue especially constructed with a view to sustaining direct pressure; but when it is driven forwards in this manner, a violent strain is thrown on its ligamentous attachments, which they are not equally calculated to resist. The internal limb of the segment suffers little, for its half of the stress is rapidly weakened and toned down by its attachment to the coronary and internal lateral ligaments by its length, and above all by the direction of the strain, which would tend only to straighten out the curve of the posterior cornu. The outer limb, on the other hand, must suffer severely. Here, without anything to break or even modify the violence, full half of the strain falls directly on the attachment of the anterior cornu, stretching it or even partially tearing it from the bone, and causing the extreme pain and the rapid effusion; and this accounts for the occasional prominence on the front of the joint when the cartilage is completely displaced, and for the exceedingly tender and accurately defined spot which corresponds precisely to this attachment.

In treating a sprain, as in everything else, a definite and accurate diagnosis is of the utmost consequence; but I am afraid the smallest things, perhaps because they interfere mainly with amusements, are sometimes the most baffling. Nothing is more easy in a young and healthy adult than to assist the absorption of a slight synovial effusion; nothing more difficult than to prevent its recurrence when the same causes are allowed to work. Of course, if people will abstain from lawn tennis after meeting with an accident of this kind and use reasonable care for some time, there is a fair amount of hope that the same mischief will not return, though I regret to say I have known it brought back, in a very much aggravated form, by

a single game after two years' complete abstention. Carefully strapping the joint would probably be the most effectual method, but I scarcely think it probable that many patients would be found willing to submit to it. The only mechanical contrivance that I have found to be of any service, and that only with complete abstention from fast play and in those who will be sufficiently watchful, is an accurately made knee-cap, preferably laced, with a pad in the popliteal space, and another over the internal semilunar cartilage, to be worn, of course, only during play. The inconvenience is great, and the interference with play so considerable that some may prefer leaving it off altogether; but the danger is so real that that alternative is, I believe, the only one.

Porchester-terrace, W.

ON AN EASY METHOD OF POSTERIOR RHINOSCOPY.

By W. J. WALSHAM, F.R.C.S.,

Assistant-Surgeon and Demonstrator of Practical and Orthopedic Surgery to St. Bartholomew's Hospital.

THE importance of making a rhinoscopic examination of the naso-pharynx and posterior nares in diseases of the nose of a doubtful nature cannot I suppose be questioned, and that considerable difficulty under ordinary circumstances attends such an examination few who have practiced posterior rhinoscopy will, I venture to think, deny. Much may, of course, be learned by passing the finger behind the soft palate; but I question if an ocular inspection in addition to a digital examination is not in some cases essential for arriving at a correct diagnosis, or, at any rate, an accurate knowledge of the extent and character of the disease. Although, no doubt, practice, as in all things, will enable us to a great extent to overcome the difficulty of obtaining a view of the parts, even then, except in favorable cases, much patience and perseverance on the part of the surgeon, and education in the manner of breathing and controlling the palate on the part of the patient, are necessary. So well recognized is this difficulty that many ingenious instruments for hooking forward the palate, etc., have from time to time been invented. None, however, have proved of much help in my hands, at any rate for obtaining more than a momentary view, and, consequently, for demonstrating to my class any morbid conditions that might be present. "The principal difficulties in rhinoscopy," says Dr. Morel Mackenzie, "consists in the unusual length and breadth of the uvula, or a too short distance between the anterior pillars of the fauces and the posterior walls of the pharynx. The former obstacle may be overcome by following the directions above given, but the latter is insuperable. In a certain number of cases," he goes on to say, "it is quite impossible to practice rhinoscopy, and it is generally easy, by examining the fauces and observing whether this space exists, to tell beforehand whether an inspection of the nasal fossæ is possible." By the following method I have in all cases succeeded in overcoming this difficulty, and in making a complete, and if necessary, a prolonged, examination of the parts, with no or little annoyance to the patient. On looking up the subject I find that I can claim little originality for the method, as a somewhat similar procedure has been adopted by some American surgeons. As my method differs, however, in what I consider an

¹ The Use of the Laryngoscope, third edition.

essential point—viz., that in its use no instruments are required—and, as far as I am aware, is not generally known or used; and, moreover, as I have myself found it of much service, especially for purposes of demonstration, it appears worth while calling attention to it. A piece of soft red rubber tubing, about one-eighth of an inch in diameter, is introduced into one nostril, and pushed very gently along the floor of the nose till it presents just below the soft palate. It is then gently seized with a forceps, drawn out through the mouth, and loosely tied across the upper lip to the end protruding from the nose, the elastic tube being stretched just sufficiently to loop upwards and forwards the soft palate, and draw it well away from the posterior wall of the pharynx. The looping of the palate on one side is often sufficient; but a better view is obtained by passing a tube through the other nostril and looping up the soft palate of that side in the same way. The posterior nares and naso-pharynx can now be examined with the ordinary laryngoscopic mirror with the greatest facility. One hand only is required to hold and direct the mirror (the stem answering the purpose of a tongue depressor), the other hand is consequently free to perform any manipulation or operation that may be required. The tubes serve as a good guide, as they can be followed in the mirror winding round the upper surface of the palate, and so into the respective choanæ. The introduction of the tube causes hardly any discomfort or annoyance to the patient. Care, however, should be taken in passing the tube to let it only just present below the soft palate, as otherwise, if it is pushed further, it may impinge upon the lower pharynx, and is then apt to produce a tickling sensation and desire to vomit. When the examination is finished, it is better to withdraw the tube through the mouth rather than through the nose, and when the nasal end is just about to drop into the pharynx to give it a sharp whisk forwards. If it is withdrawn through the nose, the mouth end trails along the tongue, causing a tickling of its posterior part.

In place of the red rubber tubes, the American surgeons referred to use flat tapes or narrow bandages for tying up the palate. These have necessitated the use of various instruments for passing them, such as the Eustachian catheter, Balloco's sounds, etc. The advantages I claim for the red-rubber tubing is that it is soft, non-irritating, and possesses just sufficient resistance to enable it to be passed through the nose by itself, thus dispensing altogether with the use of an instrument, the passage of which, as for instance in plugging the nares, is, as is well known, a source of much discomfort and annoyance to the patient.

Weymouth-street, W.

ON THE HISTORY OF FEVER IN THE ROYAL NAVY.¹

By SIR WILLIAM SMART, K.C.B., R.N.

THE author gave a sketch of the sanitary history of the navy up to the present time, exemplified by the greater or less prevalence of fevers at various periods, showing how much that class of diseases was answerable for the failure of numerous expeditions, and the cause of incalculable sufferings and loss of life. From 1585, when Drake lost 750 out of 2,300 men by yellow fever in the West Indies, and again in 1594, when Drake and Hawkins fell victims there, up to 1794, when Sir John Jervis

and Sir Charles Grey reduced the French islands, probably not less than 100,000 men were sacrificed by yellow and remittent fevers alone on that single station. On the home station, from the Thames to Gibraltar, from the days of Howard and Drake to the end of the Seven Years' War with France and Spain, not less probably than 150,000 men were lost by typhus. The former were from tropical endemic malaria, and the latter from contagion received from the gaols on shore, and disseminated from ship to ship, and dispersed around the coast towns at which the sick were landed; but it soon died out when carried to tropical climates, whilst the West Indian fevers were never brought to England. In each there was an essential cause—in the former the product of vegetable, and in the latter of animal decomposition—much aggravated in its intensity in ships by overcrowding, foul atmosphere, defective nutrition, and inattention to cleanliness of person and of locality. From French naval history it is learnt that from the same causes their fleets suffered, at the same period, even more terribly than our own. For example, in 1757 a large fleet infected with typhus left Brest for the protection of Louisburg, and returned to it in 203 days totally disabled by typhus, by which the town was infected grievously through five months, with a loss of above 10,000 lives, including five physicians, 150 surgeons, and 200 priests, which far exceeds anything in our own annals from a similar cause. Two years later the fleet under Sir E. Hughes which defeated that of Admiral Confans was at sea six months before the battle took place, and yet on the day of it there were only twenty-four sick out of 14,000 men, owing to their having been kept well supplied with fresh meat and vegetables. In fact, whenever, before or after that event, fever and flux committed ravages, there was always the scorbutic diathesis undermining the general stamina of the men. The first and second voyages of Captain Cook—1768 to 1773—afford a contrast: in the first, with scorbutic diathesis, 35·7 per cent. of the crew died of tropical fevers with flux in four months; but in the second, only one man died of disease in three years, under sanitary and antiscorbutic precautions. These are facts typical of the period. From that time, however, there was much less of fever, as before the next naval war, 1778 to 1782, the sources of fevers were cleansed by improved management of the gaols, and by improvements in the ventilation and the cleanliness of ships, but the causations of scurvy remained unmitigated, notwithstanding the experience of Hawke's fleet. In 1759-60 the admissions to Haslar for fever were 393 and for scurvy 119 per 1,000 of all admissions; but in 1782 there were 329 and 112 respectively, showing a larger proportional abatement of fever than of scurvy; and in 1780 the Channel fleet, after a ten weeks' cruise, returned with 2,400 men sick of scurvy, proving that the causes of scurvy were as rife as ever, while the causes of fever were less so. From that period, however, there was a considerable abatement progressive in both; but at no period was it so marked as immediately after the mutiny in 1797, which was followed by great reforms in the quantity and quality of the seaman's rations and pay. In proof of this, the data from the same source show that in 1796 the admissions were in the ratios of 257 per 1,000 for fever and 74·5 for scurvy, and that in 1799 they had declined to 200 and to 20 per 1,000 respectively, being a rapidity never before experienced, and that, too, in war time. In the last century, and that very late in it, scurvy disappeared in its epidemic type, and epidemic typhus has been unseen since, on account of reforms that have acted preventively, as soon as the propriety of them has been recognized.

¹ Abstract of a paper read at a meeting of the Epidemiological Society.

Superior means of ventilation have been invented; cleanliness of ships and of persons has been enforced; while overcrowding, by reason of employing larger ships in proportion to the crews, has been lessened; iron tanks have been substituted for wooden casks for water; and a very progressive improvement in the food, in quality and in variety, as regards both fresh meat and vegetables, has taken place wherever possible. Cinchona was given until supplanted by quinine as a preventive of fever; lime-juice, as a preventive of scurvy; and more frequent intercourse on shore has produced cheerfulness amongst the seamen; while the half pint of spirits allowed daily in the last century, encouraging if not legalizing drunken habits, has been abolished save on emergencies, and sobriety is no longer the rare virtue it was formerly in the navy; and, finally, the employment of iron instead of wood in naval construction, and the use of steam as a motor power, render long detention at sea unnecessary—all these changes have combined to make the navy as healthy as life on shore. The last century was, in a medical sense, devoid of experimental spirit in the navy, while such cannot be said of it since the dawn of the present century, when medical officers first began to obtain a recognized position in its ships and service.

The latest hospital statistics, from 1869 to 1877 inclusive, yield, at Haslar and Plymouth, 51,584 total admissions, with 2,539 for fevers of all types, and no scurvy, being less than 50 per 1,000, showing a decline of 150 cases per 1,000 since 1799; and of mortality from 70·5 to 60·5 in each 1,000 cases of fever, exhibiting the extent of mitigation as regards febrile forms of disease in the present century.

It is to be lamented, for the good of the service, that hospital returns ceased in 1877 to be published, thus precluding useful and encouraging comparisons in future.

LUMBAR COLECTOMY.

By CLELAND LAMMIMAN, F.R.C.S. Eng.

THE operation called lumbar colectomy seems likely in the advance of abdominal surgery, to become a generally adopted one, and as since its introduction it has only been performed on one or two occasions, the following notes of a case upon which I have recently operated may prove of some value to any who are purposing to pursue this method of relief in cases where the position of the stricture can be settled as lying in either the upper part of the sigmoid or in any part of the splenic flexure of the colon.

I first saw Mrs. —, with Dr. Ivers of Tonbridge, on Feb. 2nd (Friday), when the following history was given:—On the previous Sunday she failed to effect her usual morning evacuation, and towards the evening had some amount of distress, when vomiting came on. Dr. Ivers had given several doses of purgative medicine without effect, and had succeeded in passing O'Beirne's tube into the bowel (its whole length apparently). She had taken only fluid food in small quantities with opium. There was no history of cancer.

Physical examination.—A well-nourished woman of fifty-four years, dark, somewhat sallow, and inclined to obesity. Abdomen not tender, but filled with flatus, which could be perceived rolling the intestine over and over with loud noises. No tumour could be detected; no hernia. No evidence of anything wrong in rectum. She informed us that upon several occasions, which had increased in frequency lately, she had had great pain in her ab-

domen, with constipation and vomiting, once or twice with jaundice.

Concluding that we were dealing with an occlusion of the intestine, we resolved once more to give a competent purgative, hoping that the case might yet turn out to be fecal impaction. This produced in an hour or two some very suspicious-looking vomit. In the meantime, we introduced O'Beirne's tube into the rectum, and apparently into the sigmoid flexure, as the whole tube, save an inch or two, was passed in; but when we injected gruel, we found that not more than half a pint was retained, the rest flowing out as it was injected. Now, as at the operation the stricture was found in the upper part of the sigmoid flexure, it is plain that the tube must have turned upon itself. There was during this period and up to the time of operation no fever. After the stercoraceous vomit had appeared, we used no food, save ice in small quantities, by the mouth, using by the rectum the juice of raw meat expressed by the tincture press, and Carnrick's peptonoids, with which latter we were very pleased. Small quantities of morphia were used hypodermically twice in twenty-four hours.

We advised colotomy at once, and should have selected the right loin because of the distance to which the tube was introduced, but the patient would not consent, resolving to have Mr. Bryant down to see her. On Sunday, Feb. 4th, that gentleman came down, and he concluded that an operation should be performed without delay; but, impressed with the fact that we should, notwithstanding the passing of the tube, find the stricture in the descending colon, he directed me to open the left loin, and, if not then successful in finding the stricture, to draw down the bowel through the wound and search for it; if not finding it there, to reject the left, fasten up the wound, and proceed to open the bowel on the right side. And he added, "When you come down upon the stricture, after fastening the upper aperture of the bowel in the usual way to the skin, proceed to remove the stricture itself. I have once done this, and am satisfied that it will soon be the usually adopted operation for this trouble. I would call it colectomy."

The patient obstinately refused the operation until Feb. 14th, when without food by the stomach for seventeen days, she was manifestly going downhill; there had been no rise in temperature. On this day, having at last prevailed upon her to allow something to be done to give her a chance of life, which seemed now almost hopeless, with the assistance of Dr. Ivers, Dr. Hawthorne, of Tonbridge, and Mr. W. Rix, of Tunbridge Wells, I proceeded to operate. Dr. Hawthorne administered a mixture of one part absolute alcohol, two parts chloroform, and three of ether, on a list cone; it answered admirably, and after one hour during which the operation was proceeding, it still acted well and did not depress. Making the usual incision, six inches long, half-way between the last rib and crest of the ilium, I dissected as quickly as possible down to the fascia transversalis, but having to deal with very free hæmorrhage my progress was somewhat slow, as I had to tie many vessels as I went on. Then, having cleared the fascia through the whole length of the wound from muscle and fat, I divided the fascia transversalis upon the director and my forefinger. Now, having scraped away a large quantity of sub-colic fat, I came upon the intestine, not a distended but a collapsed one, and speedily found the stricture itself just at the bottom of my incision, now some inches deep. My colleagues assisted me in raising the gut to the surface, but it was not an easy matter, for it did not leave its bed as I had hoped it

would; it required much patience and gentle force to accomplish this. At last, having freed enough of it, I opened the intestine above the stricture, fastened it to the skin, and having placed a very stout ligature of carbolized catgut round the gut below the stricture, I cut the latter completely away. Having to our satisfaction concluded that all hæmorrhage had ceased, I cut off the ends of the ligature short, and returned it into the abdominal cavity with the lower end of the intestine, fastened up as much as seemed necessary of the wound, and placed the patient in bed, with warmth to the head and feet and a small hypodermic in the arm.

Upon examination the stricture proved to be scirrhus, and the aperture so small that it would hardly admit a probe. In the course of an hour or two a large amount of fecal matter passed through the wound, but the patient was so weak from her starvation that for hours we could not rally her from the prostration following the operation, which but for this I am convinced would have been successful. She sank about forty-eight hours afterwards. No post-mortem examination was made.

Tunbridge Wells.

ANOTHER EPIDEMIC OF TRICHINOSIS NEAR THE SOURCES OF THE JORDAN.

By JOHN WORTABET, M.D.,

Physician to the Hospital of the Knights of St. John, Beyrout, Syria; Corresponding Member of the Epidemiological Society, etc.

In a paper which appeared in *THE LANCET*, in 1881, I gave an account of an outbreak of trichinosis from eating the flesh of a wild boar, near the sources of the Jordan. Two hundred and sixty-two persons ate of the animal (November 25th, 1880), and when I visited the place of the disaster at the beginning of the new year five had already died, and the rest were more or less ill with the disease. One more died afterwards, and I succeeded in obtaining from the body a piece of muscle, in which I found trichinæ in great abundance, and thus verified the nature of the epidemic. This death happened about the fiftieth day after infection, and the trichinæ was still non-encysted. A few weeks after one of the victims came into the hospital for a slight operation in the eye, and he allowed me to take out a minute piece of muscle from the calf of the leg for examination. It was about the hundredth day after infection, and I found the parasites in as great abundance as before, but they were all by that time encysted. From frequent communication with the place, I heard that in few months all the sufferers gradually recovered, the last symptoms being slight muscular pains and general debility. Another outbreak of the same nature has recently occurred in Ain-Kiniah, near Banias (the ancient Cæsarea Philippi), and a young medical man, a former pupil of mine, who was called to the scene of the epidemic, has sent me the following particulars:—"About the 1st of March of this year a fine boar was shot in the marshes of the Jordan, and brought to Ain-Kiniah, and a part of it was sent to three other neighboring villages. Some forty or fifty persons ate of it, and they were all taken ill between the fifteenth and twentieth day afterwards. The general symptoms in every case were the same: muscular pains, œdema, and fever. The muscular pains were not limited to the extremities, but extended to the muscles of the face, the lower jaw, the neck, and abdomen. The œdema was often very great; in one case the face was so swollen that

the eyes were closed, and in an infant the general œdematous state of the body was such that its life was despaired of. The fever always increased at night. It is strange to say that not one of them died, and that they are all in a state of convalescence.

It appears that this is the third outbreak of trichinosis which has happened in those parts in recent years, the first having taken place about 1868, though wild boars are numerous in the jungles of the Jordan, and often shot and eaten during the winter and early spring. The flesh is always eaten in that part of the country in a raw or imperfectly cooked condition, and this accounts for the fact that no one who eats it escapes infection. In the outbreak of 1880 there was a remarkable exception in the case of the head of the infected animal, which was very thoroughly boiled before it was eaten, and of all the persons who ate of it not one showed any sign of the disease.

Note.—It is remarkable that there is a general unanimity among Eastern nations as to the unwholesomeness of pork. It is interdicted in the sacred books of the Hebrews and Mohammedans; and among the ancient Egyptians—from whom the Hebrews borrowed many of their sanitary laws—the pig was an emblem of Typho, the god of evil, and was held by them to be unclean and abominable. From personal observation and experience I have found the use of pork in Syria decidedly unhealthy. The wild boar in winter is a delicacy, but unless previously examined with the microscope, according to German law, or cooked more thoroughly than is usually done, its use cannot be free from the danger of communicating trichinæ to man.

SPINA BIFIDA SUCCESSFULLY TREATED BY INJECTION, AND EXAMINED POST MORTEM.

By NOBLE SMITH, F.R.C.S. Edin.

Surgeon to the All Saints Children's Hospital, and to the Orthopædic Department of the Farringdon Dispensary.

A. W—, aged two months, was born with a deficiency of the arches of the lowest lumbar and upper sacral vertebrae. The size of the tumour was in circumference at the base $8\frac{1}{2}$ in., from side to side over the tumour $5\frac{1}{2}$ in., from above downwards $4\frac{1}{2}$ in. The tumour was fully distended, translucent, and presented an ulcerated surface in the centre, secreting fluid. There was no appearance of large nerves in the sac. The right leg was small, deficient in muscular power, and the foot was affected with talipes valgus, but in other respects the child appeared to be healthy. I punctured the tumour with a No. 3 trocar low down upon one side, drew off two ounces of clear, straw-colored fluid until the tumour was diminished to half of its original size, and injected forty minims of Dr. Morton's iodo-glycerine fluid, and closed the opening with collodion and plaster. The constitutional disturbance was severe for twenty-four hours, after which the tumour began to cicatrize, and gradually shrivelled up and became like a piece of rough puckered leather. The operation was performed upon the 5th of September, 1877, and in twenty-five days the tumour consisted only of rough thickened skin, which was slightly protuberant from the surrounding surface. A part of the wall of the sac the size of a shilling remained there, and apparently unaffected by the injection. This could doubtless have been destroyed by a second injection, but the mother refused to allow another operation because her child had seemed to suffer so much from the first one. The treat-

ment was so far perfectly successful, and I anticipated a satisfactory progress of the case, although I should have preferred completing the transformation of the wall of the tumour.

In February, 1878, nearly six months after the operation, hydrocephalus made its appearance, and ran its course in two years, at the end of which time the child died. I was permitted to make a post-mortem examination of the spina bifida. Externally the remains of the tumour appeared as thickened and puckered skin, and resistant to the touch. At the centre was situated a small patch, less than the size of a shilling, of thinner skin, beneath which could be felt a small cavity. Upon dissection the remnant of the tumour was found to consist of very dense fibrous cicatricial tissue, in the form of fibres and bands passing in all directions, and closely united together. The deficiency in the wall of the spinal canal was blocked up by this cicatricial material, but with difficulty a very small probe could be passed along a tortuous passage leading from the small cavity, already referred to, to the canal. There be no doubt that a second injection would have completely obliterated this small cavity and its connection with the canal, and have rendered the tumour more thoroughly solid. The cicatricial tissue did not extend beyond the opening into the canal, but it formed a remarkably firm wall in place of the deficiency of bone. I could not discover any nerves passing from the canal to the wall of the sac.

The result of this examination seems to me of value, as supplying a proof that an efficient closure of the deficiency in the vertebræ can be effected without encroachment upon the spinal canal.

ON THE SAFE ADMINISTRATION OF BICHLORIDE OF METHYLENE.

By WM. MARTIN COATES, F.R.C.S. Eng.,
Senior Surgeon to the Salisbury Infirmary.

SOME months ago a paper appeared in *THE LANCET* from my pen on the "Safe Administration of Chloroform." From the inquiries I have received about my mode of administration and the inhaler used from every part of the United Kingdom and distant parts of Europe, I conclude that my contribution has attracted much attention, and I sincerely hope that many lives will be saved by my earnest appeal to the profession to take into serious consideration the necessity for using anæsthetics, as they do other potent agents, in the smallest dose capable of producing the desired result.

In the communication referred to I stated that by putting into Snow's inhaler, modified by Matthews Brothers, first five minims of chloroform, then in twenty seconds ten minims, in forty seconds fifteen minims, and the latter quantity every minute, I produced complete insensibility to pain with a total quantity varying from twenty minims to seventy-five, with, I believed, perfect safety, and with a great diminution of the struggling and subsequent after-nausea and vomiting. I have also found the best means of remedying the struggling or failure of the pulse in the introduction of thirty minims of pure ether by the same inhaler. I promised in the same paper to work out in the same manner the absolute and comparative power of bichloride of methylene. I have since then, both in private and hospital practice, administered the bichloride of methylene with the same apparatus, but without the hot water between the compartment containing the anæsthetic and the outer jacket of the instrument, with the following

most satisfactory results. In almost every case the bichloride of methylene was as efficient in the same small doses as an anæsthetic as chloroform. The heart's action in no case failed in the slightest degree, the struggling was less violent, and the after-nausea and vomiting were very much less troublesome. I recollect only two cases where they were present out of a great many administrations. To show that I did not select my cases I will shortly relate two.

CASE 1.—A man, aged seventy, but looking much older, had a very suspicious tumour on and extending under the left part of the body of the lower maxillary bone. He had considerable insufficiency of the mitral valve. Mr. Harcourt Coates operated. It was foreseen that a careful dissection would be required, for the tumour dipped into and among important structures under the angle of the jaw. The operation lasted half an hour. I administered methylene. Anæsthesia was obtained by forty-five minims, and kept up by ten minims poured into the inhaler whenever unconscious movements occurred. The quantity used was seventy-five minims in all.

CASE 2.—A man, aged forty-nine, with largely consolidated apex of his left lung, with crackling on coughing, under the care of Dr. Coates in a medical ward of the Salisbury Infirmary, suffered from intense pain in defecation. On examining the rectum with Curling's speculum, we saw pus oozing from an opening about an inch and a half from the anus. I decided to make an incision through the abscess, and to divide by the same incision a few fibres of the sphincter ani. This man inhaled 125 minims of bichloride of methylene before he became unconscious, and there was considerable struggling. I performed the operation. He soon recovered his consciousness, and was entirely relieved from pain. Mr. Wilson, our house-surgeon, reported to me that he had suffered no unpleasant after-effects from the anæsthetic. This is the largest quantity required by any patient.

I cannot conceive two more unfavorable cases for anæsthesia, yet no symptom of danger arose. The struggling in both cases ceased on administering through the inhaler thirty minims of ether. The absence of failure of the heart has been mentioned in this mode of giving small but efficient doses of this agent, as also the great comparative absence of nausea and vomiting. I have observed that the patients under bichloride of methylene became much sooner conscious when the inhalation was discontinued than under chloroform. In this lies the comparative safety and weakness of the bichloride of methylene. It does not in some cases abolish so completely the reflex functions as does chloroform, and in two cases of operations on the rectum, where the reflex action is so easily excited, fifteen minims of chloroform were substituted for the methylene, with immediate advantage. For the same reason I can conceive that in delicate operations on the eye or its appendages chloroform would be better than bichloride of methylene. This is a point I shall test with some anxiety, as in some eye operations vomiting is a matter of great importance. I allude of course to extraction of cataract and iridectomy. In the removal of a sightless eyeball from injury I found the bichloride of methylene in an old man quite as effective as chloroform, and, I feel sure, freer from danger. As my plan, no doubt, has been tried by many, and no contradictions have come from any quarter, and as no death has occurred or been reported under this mode of administration of chloroform or bichloride of methylene, and as, moreover, it is in strict accordance with the principle universally acknowledged and adopted with all other potent medical agents—viz., to confine

ourselves to the smallest dose capable of producing the result aimed at—I sincerely trust that in the interest of their patients and of themselves medical practitioners will give this mode a fair trial and record the results. Anyone not doing so, and having a fatal case, would be most painfully situated, I should think, at the subsequent coroner's inquest. My conviction is that the danger from chloroform and bichloride of methylene is so minimized by this method, if closely adhered to, that they may be used with the most perfect confidence in persons free from organic disease; and, if I may judge from my own practice, in cases in which we should not have dared to do so—i.e., in cases of advanced organic disease of heart or lungs. The repeated small doses by their insistence on the attention of the administrator might, if necessary, as a gentleman who came from Birmingham to witness this mode said, be advanced as an additional source of safety. I must repeat, in reference to the bichloride of methylene, what I advanced as to chloroform, that as some persons are very easily affected so there are others who require increased doses (twenty minims per minute), though this is very rare.

I may here add that I formerly used Junker's inhaler, but it has not the accuracy of the one I use now; and there is the disadvantage that a quantity of the vapor remains in the atmosphere of the operating room, and so becomes a source of danger. It has been proved on every occasion when looked into that the whole of the fifteen minims of the anæsthetic have been consumed at the end of each minute with the instrument used by me. I trust that my medical brethren will not think that any of my utterances in this paper have been too strong; if so, I hope that in extenuation they will consider my deep conviction that some, perhaps many, lives must be sacrificed if the adoption of small doses be not made general.

Salisbury.

NOTES AND REMINISCENCES OF A CHOLERA EPIDEMIC AT KOTREE AND HYDERABAD, SCINDE, INDIA.

By JOHN ROCHE, M.D.,

Retired Surgeon, Bombay Army; formerly Civil Surgeon, Kotree; Civil Surgeon, Hyderabad; Vaccination Superintendent, Scinde and Mahratta Circles, etc.

CHOLERA attacked the laborers who were engaged in canal digging near Hyderabad in August, 1869, having been for some time previously amongst the inhabitants of Thurr and Parkur to the south-east of Scinde. On September 3rd, 1869, the first case was reported at Kotree, as being in a village about three miles to the north, on the right bank of the Indus. On inspection it was ascertained that the man attacked had been suffering from diarrhoea for some time. He had been at work on the canal near Hyderabad, where cholera was prevailing, and had only arrived the day previous for the purpose of receiving the attention of his people. In two days a second case occurred in a hut close to where the first was ill (it was a woman who had been nursing the first victim), and after another few days a little girl was attacked in the same house with the woman. Notwithstanding that every effort was made to isolate the cases the disease spread rapidly through the village. On the 12th of September the first case broke out at Kotree, a town of about 20,000 natives and about 400 Europeans, being at that time the headquarters of the Scinde Railway and Indus Steam Flotilla, with workshops and the Settlement Survey of the Right Bank Division of Scinde. The case was

a policeman's wife, who came from Hyberabad to visit her friends the night previous. The other cases, which soon followed, were traced distinctly to contagion from this source. Personal intercourse and association were traced between those early affected in the epidemic, so as to convince the most sceptical as to the infectious nature of cholera. There was no predisposing cause that could be discerned, excepting that there was an excess of rain and floods in the preceding months, and that the air in September was unusually sultry, still, and moist. There was no defect in the water-supply, nor was there any insufficiency or deterioration in the food of the inhabitants. Amongst a population embracing many castes, the lower orders were more amenable to the disease than those who could live in comfort; but one caste following a particular occupation or existing on a specific food was not affected more than another. The Europeans escaped comparatively well; only three were attacked, two of whom were intemperate in habits and died. They became literally panic-stricken directly the cholera made its appearance in the locality. The symptoms were the usual ones: vomiting and purging, first of contents of alimentary canal, next bilious matter, afterwards whitish rice-water discharge; cramps, epigastric heat, burning thirst, a semi-intoxicated state of the nervous system, præcordial anxiety, coldness of surface of body to the touch, choleraic voice, the eyes sunk in the sockets, and collapse. Death was preceded in most instances by a very offensive, tarry evacuation. The temperature in every stage, as taken in the axilla and the thermometer held well covered for above ten minutes, was over 99°, and in some cases in what is written as the algide or collapse stage over 100°. At this time this phenomenon had not been promulgated, as far as I could learn, so as to ensure credence. I secured Major (now Major-General) Malcolm Haig to witness it in two Europeans in different degrees of collapse, and whose bodies were extremely cold to the touch, and whose temperature, taken by the application of the instrument for two minutes, did not register more than 94°. I solicited Surgeon-Major Nolan, M.B., H.M.'s Bombay Army, to observe the rise in temperature attendant on covering and on excluding the cold air, who deemed the fact of great importance. It led me to conclude that cholera was purely and simply a specific fever, only inferior in its ravages to yellow fever, and closely allied to it.

There were altogether about 700 cases of cholera in a period of over two months, about 400 of which were treated directly by myself. The severity of the type has scarcely ever been equalled; 86 per cent. of those attacked were fatal. The duration of the disease varied from half an hour (there were two cases that never vomited or purged, that fell down with all the signs of cholera and died in less than half an hour) to three days, when, if the patient survived, remittent fever of a typhoid character supervened. The eyes were in some instances affected, and in three the recoveries were marred by blindness. A port-wine-colored discharge was also a harassing complication.

The detailed reports of some forty cases, which I closely observed from commencement to termination, were forwarded to the Inspector-General of Hospitals at the time at Bombay, and also a full history of the epidemic, in which I satisfied myself of the truth of my contention against the fungus theory of Kloba, Bary, and Hallier, and the peculiar underground theory of Kölliker, as utterly unsound, towards the end of the year 1869, some months before Messrs. Lewis and Cunningham furnished theirs, which condemned the fungus theory.

I stated then, that I had found the temperature in every stage raised when observed according to my directions, the capacity for resisting the abstraction of heat by surrounding elements diminished, the absorbents devoid of function, and the excretory organs much impaired. I have observed a similar condition of things following snake-bite, as published in a case by me in Fayer's "Thanatophidia of India." The antiseptics (carbolic acid, sulphites, and quinine) had no beneficial action in treatment. Alkalies, acids, and metals availed not much, and ether and ammonia seemed not of great importance. In the collapse stages internal medicines were not apparently absorbed. The only applications which responded to any hope were sinapisms to the epigastric region, with mustard and turpentine frictions to the seat of cramps; and in the reaction, or recovery stage, by treating the disease purely and simply as a remittent fever, with quinine, arsenic, ammonia, and bark, with diaphoretics and cholagogues; ipecacuanha and antimony in small doses often repeated seemed most beneficial in the port-wine-colored diarrhoea, which in many cases was a rebellious complication. Particular cases are gone into in my original report, and therein is a clear refutation of any other theory of cholera than that it is a malignant fever subject to epidemic and endemic influences. Cholera has a period of incubation varying from two to fourteen days; prone to attack the enervated and those subject to depression from any cause. It is contagious, and liable to occur periodically about every ten years in some parts of India. It seems to have visited the British Isles about every sixteen years, and as the period has elapsed since the last outbreak, it is more than likely to occur this year. The affection has a predilection, or wears its virulence out amongst a people. A fortnight after the last case occurred at Kotree a number of Afghans arrived, and there were some of the worst cases amongst them, but not one of the inhabitants of the town then took the malady. Those persons who indulge in no enervating habits, and take nothing internally which would arrest the secretions nor too drastically stimulate them, and partake of nothing which is highly fermentable, may safely feel that they are cholera-proof during an epidemic.

ON FIFTY CASES OF TURNING.¹

By F. H. V. GROSHOLZ, M.K.Q.C.P.I., Etc.

It is not my intention to give a detailed account of each individual case of the fifty in which I have thought it necessary to perform the operation of version, as, though such minuteness might prove not altogether uninteresting nor entirely unprofitable, yet doubtless a summary of the facts and the deductions to be drawn therefrom will more graphically, and at less expense of time, effect the object I have in view—viz., the consideration of the causes which demand an artificial termination of labour by the aid of turning, the results of that operation as regards both mother and child, the method and time of performing the operation, and the lessons which are taught by its results, whether successful or otherwise.

First, then, as to the causes which necessitated version. As turning is generally understood to mean a restoration of a child to its normal position in the uterus, or the substitution of some other portion of the body for that originally presenting, it will not seem surprising that the operation was performed for the rectification of some malposition

of the fœtus in thirty-eight out of the fifty cases. Of the remaining twelve, five were cases of placenta prævia, four of contraction of the pelvis, and three of uterine inertia. We thus see that thirty-eight, or about four-fifths of the cases in which the operation was performed were cases of *malpresentation* of the fœtus, four of *malformation* of the mother, five of *malposition* of the placenta, and three of failure of the uterine contractions. To go a little more into detail, I have tabulated the above facts as follows:

Malpresentation	Shoulder.....	18	}	38
	Arm and funis....	8		
	Arm.....	6		
	Face and Hand....	3		
	Brow.....	1		
	Brow and hand....	1		
	Back.....	1		
Pelvic contraction.....				4
Placenta prævia.....				5
Uterine inertia.....				3

50

Secondly, as to the results of the operation as regards both mother and child. The average maternal mortality has been estimated by Dr. Churchill as 1 in 15, and the infantile as 1 in 24. In my fifty cases I have had no deaths among the mothers; twenty children were either born dead or died soon after birth. This seems a rather high infantile mortality; it is indeed exactly in the proportion above named; but as eight of the children had manifestly been dead for some time (as evidenced by signs of putrefaction more or less advanced), it is hardly fair to class their death among those due to turning. Omitting these, the proportion of dead children delivered by version is reduced to 1 in 34, which I consider a very fair average. Of the other twelve children which were born dead, two were cases in which the funis was prolapsed; two in which there was placenta prævia; and the remaining eight may be roughly classed together as owing their death either to a disproportion between the maternal pelvis and the infantile cranium, or to a too prolonged compression of the umbilical cord. One woman was only twenty years of age, and another as old as forty-five. One child weighed 13 lb. 2 oz.; and one, which lived nearly two days, weighed only 2 lb. 1 oz.

Having enumerated the causes which demanded version, I will next briefly remark on the signs by which I have been guided in the selection of the time which seemed most favorable for performing the operation. In every labour all obstetricians will concede that it is of the utmost importance to become acquainted with the exact position of the child at the earliest possible opportunity. Where there is a malpresentation, its early discovery is of the greatest importance, for before the membranes are ruptured not only can turning be performed more easily, and with less risk to the mother, but the chances of the child's life are also much increased. After the membranes are ruptured, the danger to both mother and child becomes greater and greater as time goes on. Indeed, no cases require such gentleness, patience, and persevering courage on the part of the operator as those cases of malpresentation in which the membranes have long been ruptured, and the uterus is closely contracted around the fœtus, pressing it more and more firmly down into the pelvis. In cases where the os has not been sufficiently dilated to admit the passage of the hand, and where a speedy termination of labour was essential, I have found very satisfactory results from the practice of gently and gradually dilating the os by passing the tips of the thumb and two

¹ A paper read before the North Wales Branch of the British Medical Association, July 3rd, 1883.

fingers within it, and have by their aid, without the use of anything like undue force, frequently been able to effect a comparatively speedy dilatation. In two cases I used Barnes's dilators, and they most fully answered my expectations. I need hardly say that Braxton Hick's method of version by combined internal and external manipulation not only greatly facilitates the operation, but also enables us to perform it sooner than would be justifiable were it necessary to introduce the whole hand within the uterus. Indeed, if called to a case of arm-presentation, in which the membranes are unruptured, and the os, though small, is soft and dilatable, I see no reason to defer the operation, for, in awaiting the fuller dilatation of the os, you run the risk of a sudden rupture of the membranes, thereby losing the chance of an easy, safe, and successful termination of the case.

Having now cursorily considered the period at which it is best to perform version, I will proceed briefly to describe the manner in which I usually perform the operation. The ordinary obstetric position (the patient lying on her left side) is, I think, preferable to any other, though in a few very difficult cases where the abdomen of the child was placed anteriorly, and where the liquor amnii had long escaped, I have found it advantageous for the mother to lie on her back, and have thus been more easily able to pass the hand over the child's body. In nearly every instance I use the left hand, as I think it much more readily adapts itself to the curve of the sacrum, leaving at the same time the right hand at liberty to manipulate externally; then, too, the left hand is generally smaller than the right, a not unimportant point to be considered in the choice of the operating hand.

It is not necessary for me to describe the operation of version, whether it be the simpler and safer plan of turning by combined internal and external manipulation, or the more serious operation when it is necessary to introduce the hand into the uterus from which the waters have escaped, and which is firmly contracted around the child. On one or two points, however, I should like to say a few words, giving the conclusions I have arrived at from a not inconsiderable experience in this operation. As long as the operator's hand can take hold of one of the inferior extremities, it is immaterial whether a foot or a knee be seized. In transverse presentations, traction on the knee or foot of the side opposite to the presenting shoulder effects rotation more readily than by bringing down the leg of the same side. It is decidedly advantageous to bring down only one foot or knee instead of both, as in this manner the parts are better dilated, and less difficulty is experienced in the delivery of the rest of the body. Where, after bringing one foot down, the body does not readily turn, it is a good plan to pass a tape round the limb, and whilst making traction on it downwards and backwards, to attempt to push back the presenting shoulder. In placenta prævia I prefer to turn by Dr. Hick's method as soon as the condition is recognized; where it is necessary to pass the hand into the uterus, I try to do so at the point where the placenta seems least attached, and never through its substance.

Knowing the extreme value of chloroform in causing relaxation of the spasmodically contracted uterine fibres, it may seem strange that I have only used it in three cases. Unfortunately, my patients and their friends have all shown such a determined opposition to the administration of chloroform that I have on nearly every occasion been compelled reluctantly to proceed without the aid of anaesthesia. That this has greatly added to the risk of

laceration of the uterus there can be no doubt, nor that it has also added enormously to the anxiety, difficulty, and pain experienced by the operator; and, under the circumstances, I think it remarkably lucky that though there have been several cases of tedious convalescence, yet all my fifty patients have eventually completely recovered. In the three cases in which chloroform was administered it was of the greatest possible service, and I now more strongly than ever advise its use both in version and every other obstetric operation.

With regard to the relative merits of version, long forceps, and craniotomy, there is no doubt that each method has peculiar advantages in certain circumstances, and that every accoucheur should be intimately acquainted with each obstetric operation; yet at the same time none requires and deserves more careful study and practical skill than the ancient, most important, and truly conservative operation of turning.

Aberdovey.

ON A CASE OF PAROSTEAL SARCOMA OF THE RADIUS.

By HENRY T. BUTLIN, F.R.C.S. Eng.,

Assistant Surgeon and Surgeon for the Diseases of the Larynx, St. Bartholomew's Hospital.

THE term parosteal is here employed in the sense in which it is used in Virchow's "*Krankhaften Geschwülste*,"¹ to denote a tumour growing by the side of a bone, probably from the outer surface of the periosteum. Such a tumour is easily distinguished from a subperiosteal tumour; for, while the one leaves the periosteum unbroken and closely adherent to the bone, the other raises it off the bone, erodes and destroys the compact tissue, and often penetrates into the medulla or cancellous tissue.

Parosteal sarcomas are, I believe, by no means common. Among a large number of sarcomas of various bones which I have had the opportunity of examining, I have only met with two or three instances. Partly on this account, but chiefly on account of the difference which appears to exist between these tumours and those which grow beneath the periosteum, the following case appears worthy of publication. I must thank my colleague, Mr. T. Smith, for the permission to use it, for although I first saw the patient, and operated on him, it was during Mr. Smith's absence from town.

C. E—, aged twenty-four, a railway porter, a strong and healthy-looking man, was sent to St. Bartholomew's Hospital by Mr. Hall, of Tottenham, on April 8th, 1882. On the radial side of the left forearm, about midway between the elbow and the wrist, was a tumour as large as a small fist, but lobed and elongated. It presented towards the front, as well as on the outer side. The tumour was tense, fluctuating on the outer side, but firm towards the front; the skin covering it was stretched, but not discolored. In the axilla was one enlarged gland about the size of a small nut. The man said that for four months he had been conscious of the presence of a lump in the forearm; but it had grown very slowly, and without pain, and therefore had not prevented him from pursuing his occupation, until about six o'clock on the previous evening, when suddenly, without warning and without any evident cause, it began to enlarge, and in less than half an hour had doubled its previous size. The enlargement was accompanied with excessive pain, which at once rendered him incapable of continuing his work, and compelled him to seek advice. The diagnosis was sar-

¹ Band ii., s. 97 and s. 347.

coma of the radius, probably subperiosteal, which had enlarged from sudden hæmorrhage. He was put to bed, the arm laid on a rest, and cooling lotions were applied. But the pain continued unabated, and on April 10th was so intense as to call for active treatment. A consultation was held, and two of my colleagues who were in the hospital agreed in the diagnosis, and in the urgent necessity for operation. Half an hour later, after an Esmarch's bandage had been applied, I made a free incision into the tumour, turned out a large quantity of blood-clot and soft tumour substance, and found, contrary to what had been expected, that the bone was nowhere bare. The sac which contained the tumour was everywhere perfectly smooth-walled, except where the solid tumour was lightly adherent to it, and lay deep down between the muscles and around the radius, over which the periosteum lay smooth and closely adherent. Had the tumour been subperiosteal I should at once have amputated, but the immunity of the bone from disease and the smoothness of the cavity in which the tumour was enclosed tempted me, in spite of the malignant aspect of the new growth, to scoop it out and try to save the limb. One of my colleagues was decidedly of the same opinion. Every visible and tangible particle of the growth was therefore carefully removed, the cavity was sponged out with a solution of chloride of zinc (forty grains to the ounce), a drainage-tube introduced, and the operation concluded. The patient made a good recovery and returned to his work with a perfectly useful limb. In October he was again admitted into the hospital for the removal of a recurrent growth, which had been springing up during the past few weeks in the deep tissues on the ulnar side of the scar. The enlarged axillary gland had entirely subsided. The growth was removed by Mr. Smith, who dissected it out from amidst the muscles. It was not so clearly defined as on the first occasion. The patient again recovered speedily, and was able to resume his work, the movements of the limb being unimpaired. On May 16th, 1883, Mr. Smith removed a second recurrence, much smaller than the first and seated in the fascia covering the superficial flexors. The deeper parts were not affected, and even the surface of the muscle was not invaded. The operation was therefore trivial, and the patient quickly recovered.

A microscopical examination of the tumours showed that they were chiefly spindle-celled, but contained also numerous bodies like elongated nuclei, and round cells. The disease was, therefore, a spindle-celled or mix-celled sarcoma. It is, of course, too early yet to claim success for the conservative treatment which was adopted in this case. But thus far the result appears to justify the attempt, I might almost call it the experiment, to save the limb. The appearance of the first tumour was that of a medullary cancer which had been bled into, and the situation of the disease made it almost certain that it was a round or spindle-celled sarcoma. I have already said that if it had been subperiosteal I should at once have amputated. It may be asked why an attempt was made instead to scoop the tumour out. To this the reply is that the information we possess regarding the malignancy of subperiosteal sarcomas is sufficient not only to justify but to call for amputation; that, on the other hand, our knowledge of the properties of parosteal sarcomas is very slender, but there is some reason to believe that they are not so malignant as the subperiosteal tumours. We have been too much in the habit of regarding all spindle-celled sarcomas, or all round-celled sarcomas, no matter what part they affect, as equally malignant and requiring similar treatment.

I have endeavored to show* that this is not the case, and that the malignancy of sarcomas of the same kind depends very largely on their situation. The malignancy of subperiosteal round, and spindle-celled sarcomas of the radius and ulna is much less than that of subperiosteal round, and spindle-celled sarcomas of the humerus. The malignancy of central sarcomas of the radius and ulna is much less than that of subperiosteal sarcomas of the radius and ulnar; the former may be safely treated by excision or scooping out, the latter require early amputation. From many facts of the same kind it is quite clear that the application of general rules to the treatment of malignant disease of all parts of the body is of very little use, and that it is absolutely necessary that the malignant diseases of every part should be studied separately. The comparative malignancy of parosteal tumours is still unknown, and the treatment is therefore experimental. I can shortly recall one or two instances which tend to prove that they are less malignant than subperiosteal tumours of the same parts of the body.

A woman aged fifty-five years, suffered amputation for a parosteal sarcoma of the ulna, which had projected through the skin and appeared as a very malignant mass on the inner aspect of the forearm. She died from causes connected with the amputation; and the post-mortem examination showed that the lymphatic glands and viscera were quite free from secondary disease. Yet the tumour had existed more than two years, and was an excellent example of spindle-celled sarcoma.

At a recent meeting of the Pathological Society,² Mr. George Lawson exhibited a tumour which appeared to have grown from the outer surface of the periosteum of the lower jaw. This tumour was a sarcoma composed chiefly of spindle cells, and was the eleventh recurrence, ten previous tumours having been removed during a period of many years, the first by Sir William Fergusson, the last by Mr. Lawson. The few cases of subperiosteal sarcoma of the lower jaw I have been able to collect have run a very different course from this. Of two cases of spindle-celled sarcoma, of which the result was known, one patient died at the end of twenty-eight weeks, the other within a year. The parosteal tumour of the bones of the forearm may be compared with the cases of subperiosteal tumours of the forearm in the tables in my book on *Sarcoma and Carcinoma* (page 68). To the cases there tabulated I can add another, which has just been treated in the hospital by Mr. Smith. The patient was a woman, aged twenty-seven, who had noticed a swelling in the forearm only about six months, but had felt pain for a much longer period. She appeared generally a healthy person and presented no signs of constitutional disturbance. About the middle of the right forearm, and presenting chiefly on the outer side, was a fusiform tumour about five inches long, firm and smooth. The skin was not affected and the glands were normal. On July 20th the tumour was cut into, and removed by cutting and scooping. Three inches of the radius, where it was bare of periosteum and rough, were also removed. The growth, like the recurrent tumour in the first case, infiltrated the muscles. It bore all the general characters of a soft cancer without cysts and without capsule. It consisted largely of fibrous tissue, in the meshes of which were numerous round and oval cells, and I regarded it as a fibrifying sarcoma. The wound healed well and the patient left the hospital. But, three months later, in October, she returned with considerable recurrence in the parts

² *Sarcoma and Carcinoma*, 1882. Introduction, etc.

³ Feb. 20th, 1883.

above the scar, extending so high towards the elbow as to render amputation through the arm necessary. The contrast between the infiltration and rapid and extensive recurrence in this case and the circumscribed character and more kindly course in the first case, is the more striking when it is noted that the tumour in this case was much the firmer and more highly organized. Of the diagnosis between parosteal and subperiosteal tumours, I can only say that it appears impossible until the tumour has been freely opened, but may then be easily made by feeling with the fingers whether the bone is closely covered with periosteum, or whether the latter is raised and the bone at any part rough and bare.

Queen Anne-street, W.

REMARKS UPON SOME RECENT INVESTIGATIONS ON THE VENOM OF SERPENTS.

By S. WEIR MITCHELL, M.D.,

Member of the National Academy of Sciences, U.S.A.

I HAVE been much interested by Professor Badaloni's article in *THE LANCET* for July, 1883. Although what I might have said in criticism of it has been in a measure anticipated by your quotations from a recent paper by Dr. Reichert and myself, the frequent use of my name in Dr. Badaloni's and in other late essays on snake poisons, makes it proper for me to say a few words explanatory of certain parts of the subject, which run the risk of being misstudied. I am the more willing to discuss this matter in an English journal, since the English interest in venom poisons ought to be greater than ours, so long as the deaths from snake-bite in India are so horribly numerous. I may frankly state here that my own recent researches in conjunction with Dr. Reichert were due chiefly to the fact that I had become sure of the existence in my former papers of many grave errors and defects, due largely to the want of such means of research as are to be found to-day in every laboratory. I had also reached the conclusion that the complexity of the phenomena of venom poisoning was too great to be owing to one single toxic agent. The researches which began about ten months ago, and have been continued up to this time, very clearly indicate the need for another year of work before we shall be able to report fully upon the enormous range of subjects which still demand elaborate experimental inquiry. The preliminary report made to the National Academy of Sciences was therefore in some sense premature, and already we are aware that certain of its statements need modification. So much interest had been awakened in our chemical results that it seemed best to us to publish them in some shape. If they be correct, they of course set aside the analyses both of Lucien Bonaparte and of myself. My own simply separated one element of the venom; his threw down all, and separated them more or less from the saline and other harmless constituents.

Thus far we have examined the venom of the cobra, *crotalus adamanteus*, *crotalophorus*, copper head, *moccasin* (*pugnax* and *piscivorus*) and elaps corallina, our only close ally of the cobra. Before long we shall also possess living specimens of the "vipère fer de lance." So far as we have gone we have learned that the venom of all these serpents has at least three proteid constituents:—One dialyzable, and resembling a peptone, and apparently a hastener of putrefactive change, but with little power to prevent coagulation of blood. A second venom globulin, a more deadly poison, acting powerfully on blood and capillaries so as to cause enormous

local hæmorrhages at the point where the poison is injected. These two substances differ in amount and in toxic activity in different serpents, and even in different species. The globulin, and these names are to be regarded merely as labels, is destroyed by a heat of 100° in all the venoms studied. The peptone venom also varies greatly in power and probably in quantity. In our preliminary report it was said that the V. peptone of the diamond-back rattlesnake, *C. adamanteus*, was destroyed by a heat 100° C., which would leave this serpent, as regards this, in an exceptional position, because it would then appear that its peptone in this respect stood alone. It is, however, a feeblar agent than the peptone of the moccasin, and requires to be used in large doses in order to kill, so that it seems probable that we were misled in looking on it as exceptionally liable to destruction by heat. The third proteid resembles serum-albumen, and has been our greatest difficulty. It was believed at the time of the publication of our preliminary report to be innocent, but of late it has become entirely clear that it also is an active poison, resembling globulin in its mode of action.

A brief statement will make clear some of our embarrassments. The globulin is readily obtained, as it is thrown out of solution when water is added to venom, perhaps because of the dilution of the salts which kept it dissolved. Now, when diluted venom is placed in a dialyzer, the peptone salts pass out to the distilled water on the exterior, and, owing to the loss of salines, the globulin still held in solution, or an analogous principle, falls down within the dialyzer. When no more peptone or salts pass through, the globulin is separated by decantation or filtration and washing, and the serum-albumen remains in solution. The process is, however, a slow one, and especially so if conducted at a low temperature, while, if attempted at a high one, every product soon swarms with bacteria.

The study of three poisons in each serpent must of necessity involve an amount of labor which only a physiologist can appreciate; but as the matter now appears, it is more and more probable that the differences between the most distant genera of *Thanatophidia* will be found to be rather in the relative amount and energy of these various elements than in any distinct qualitative peculiarities. The pathological study of the effects of the venoms will of course appear in a novel light, and already we have accumulated a vast number of interesting observations which will largely advance our views of the nature of animal poisons.

As regards antidotes, it does seem as if there had been introduced a great deal of very needless confusion. It is quite clear that there are several substances which, being mixed with the venoms, render them inert or lessen their toxicity. Some of them destroy the power of globulin and venom albumen, and leave the peptone intact. Alcohol merely precipitates, and does not coagulate these proteids, and, of course, does no good as a locally counter-active agent. A few agents destroy alike all the proteids of venom, or at least in more or less various ways make them inert. Permanganate of potassa does this, and so does perchloride of iron, while dialyzed iron, which throws down all the proteids, merely makes with them a combination which when injected into the tissues is still deadly.

Potassa has a certain amount of protective power, but not as complete as is that of permanganate of potassa, since its mixture with venom is innocuous, both in the areolar spaces and the blood, whilst the mixture of potassa and venom is only innocent in the areolæ and not in the blood, nor yet, according to Vincent Richards, an excellent ob-

server, in the peritoneum. Of course if we inject at once or very early such agents as permanganate or perchloride into the track of the fangs, and by friction cause them to come more or less into contact with the venom, they will neutralize whatever they meet, destroying alike the proteids of the tissues and those of venom, and be so far remedial; but we are not as yet in possession of any agent which will follow the venom through the economy and prevent it from killing. There is as yet no physiological antidote for venom poisons.

As regards the remarks of Dr. Badaloni on the inefficacy of viper poison in cold weather, I may say that in very cold weather all snakes are sluggish, and secrete so little, and renew their venom so slowly, that it is not surprising to find little snakes like the European viper unable to do harm in cold weather. I am sure that the poison is as efficient in cold as in warm weather. It must be a question of quantity. I have to regret the loss quite recently of a rattlesnake, eight feet and a half long, weighing about 18 lb. When he arrived, in midwinter, he threw out into a saucer over sixty minims of venom, but renewed it very slowly until the laboratory was artificially heated. If snakes be well fed and well warmed they secrete freely, but confinement, cold, and absence of food very often diminish remarkably their toxic activity and their administrative vigor.

I take this opportunity of expressing my indebtedness to Sir Joseph Fayrer, and to Mr. Vincent Richards, of Calcutta, for supplies of cobra poison. The difficulties of a research which demands hundreds of serpents of various genera and species, coming sometimes a thousand miles, can very well be imagined, and in fact were it not for the potent help and constant sympathy of Professor Baird, of the Smithsonian Institution, no individual resources would be competent to carry on a pursuit so burdened with difficulties.

A CASE OF LIVER ABSCESS, WITH REMARKS.

By EDWARD HENDERSON, M.D., F.R.C.S. Edin.,

Municipal Surgeon and Health Officer, Shanghai.

THE following case suggests one or two interesting considerations in relation to abscess of the liver.

G. N—, a Swiss, aged forty-nine, for many years resident in China, was seen by me for the first time on the 25th of October, 1881. He then gave me the following history. While living in Pekin, in the beginning of August, he had experienced some enfeeblement of his general health, accompanied by loss of voice. In the beginning of September he was confined to bed with "congestion of the liver," and suffered then from pain in the right hypochondrium. This pain was at first acute; it left him entirely after about two weeks' duration, but he still had fever. On Oct. 10th he went to the seaside (Chefoo) to try the effect of change of air, but his fever continued, and his general health did not improve. He now, at times, suffered from pain in the epigastrium, which he regarded as due to indigestion. Since Oct. 17th he had had diarrhoea, about three motions daily, watery, yellow, and offensive. He had had profuse night sweatings at irregular intervals for some weeks. He had a short, dry, frequent cough, and his voice continued very weak. He was thin, having, he told me, lost weight considerably, and he had an anxious depressed look. His temperature was 102.4°; pulse 124, weak. A careful examination showed nothing indicating disease of the lungs. The liver area of dulness was enlarged;

in the nipple-line comparative dulness began in the fifth interspace; absolute dulness on the sixth rib; dulness extended an inch beyond the margin of the ribs. In the middle line, at my first examination, the percussion note was clear quite up to the sternum; subsequently (on the 31st) I noted dulness as commencing three inches and a half above the navel. There was no fulness or feeling of increased resistance in the dull area, and absolutely no tenderness. The abdomen was moderately distended, yielding everywhere a tympanitic percussion note. The spleen was apparently of normal size. Between the 25th and 31st of October the patient's temperature was always raised, varying from 99° to 102.4° F. His pulse was very weak, beating usually 116 in the minute. The cough, diarrhoea, and night sweats continued. On the 31st the area of liver dulness had extended below the rib margin about half an inch, and comparative dulness was distinct on the fifth rib. I thought I detected obscure friction sounds in the right epigastrium, which now also seemed somewhat fuller than the left.

My patient's general condition not admitting of much delay, on the afternoon of the 31st I made three exploratory punctures with the No. 2 needle of a Weiss aspirator—viz., two in the right epigastrium, about two inches and a half apart, near the rib margin, and in an upward direction; and one in the right axillary line between the seventh and eighth ribs. These were without any result. The punctures were made with antiseptic precautions, but were followed apparently by some localized peritonitis; at all events the patient complained for two or three days of considerable tenderness in the right epigastrium, and his temperature rose to 103°, and maintained a higher range for a short time. On Nov. 5th, Mr. N—'s condition being decidedly worse, I made another attempt to reach pus with the aspirator, puncturing in the back, in a line with the angle of the scapula, and in the right axilla. These punctures were also without result. On the 7th, coarse friction-sounds were distinctly heard in the right epigastrium; and on the 10th I made another fruitless attempt to find an abscess by deep puncture in that situation below the margin of the ribs. These last two operations were unattended by any symptoms indicating increased local or constitutional disturbance. On the 18th there seemed no hope of the patient's recovery, the physical signs still indicating an abscess of the liver as the only probable cause of his illness. On the 18th I made a final attempt with the aspirator, and succeeded in evacuating about ten ounces of characteristic pus by a puncture three inches deep, and made in front between the sixth and seventh ribs. My patient's strength was now nearly exhausted, and as there was no chance of his being able to support a purulent drain, I proceeded at once to enlarge the wound, and to introduce a drainage-tube, using the needle of the aspirator as a guide to the abscess cavity. I dressed the wound, as I had operated, antiseptically. For ten days there was some improvement; the patient's temperature fell, and he took fluid nourishment well; but the pulse increased in frequency and diminished in strength, until, on the 27th, it could scarcely be counted at the wrist. Owing to the utter prostration of the patient, the antiseptic dressings were changed with difficulty, and on the 28th I suspected that they had failed; the discharge, though not putrid, was sour-smelling, and was increased in quantity; the skin also round the margin of the wound was beginning to ulcerate. The urine was now constantly dark-colored, and I changed the carbolic for a salicylic dressing on the 29th. The patient died on Dec. 6th, general blood-poisoning, carbolic acid poison-

ing, a second abscess, and ulceration of the bowel being all suspected during the last week as contributing to the fatal result.

The body was examined on the afternoon of the 6th. The skin surrounding the external wound had ulcerated, the ulcer being circular, with a diameter corresponding to the length of a safety pin used to prevent the tube from slipping into the cavity of the abscess. Scattered on the surface of the skin, in the immediate neighborhood of the wound, were several small (pea and pin's head) circular ulcers, where pustules had formed, apparently as a result of irritation produced by the frequently changed antiseptic dressings. The tract by which the drainage-tube reached the abscess traversed the diaphragm, which was closely applied and loosely adherent to the costal pleura round the wound. The base of the right lung throughout its whole extent was adherent to the diaphragm, but the pleural cavity was empty, and there were no other signs of inflammatory change on its surface. The tract made by the drainage-tube terminated in what appeared to be two distinct abscess cavities, communicating with one another, and being each about the size of a small orange; these were situated close to the spine, so close as to be well within a line drawn from the angle of the scapula behind to the point of the sternum in front. The nearest points of approach which these cavities made to the surface in front was about the spot where the drainage-tube entered; behind, and close to the spine, one of the cavities was only separated from the costal pleura by a thin layer of fibrous tissue. The liver tissue surrounding the tract made by the drainage-tube and the abscess cavities was breaking down, and infiltrated with pus. In this tissue there were several distinct abscesses, varying from a hazel nut to a walnut in size; but there were no abscesses at a greater distance than two inches from the tube-tract or one inch from the principal cavities. The liver was fatty, and weighed about twelve ounces. Opposite the right epigastrium some slight adhesions had formed between the right lobe of the liver and the wall of the abdomen. There were five ulcers in the cæcum; the largest was an inch and a half long, by half an inch wide, and disposed, like the tubercular ulcer, across the bowel; the others were smaller, and had circular outlines. The situations of all these ulcers were marked on the peritoneal surface by deep, black pigmentation in dots and patches; and this deposit of pigment led to the discovery of the cicatrix of another ulcer, the radiating white lines of which were clearly seen on the surface of the mucous membrane, although they had quite escaped notice when that surface only was examined. The lungs were free from disease, as were also the kidneys.

Remarks.—This case was at first somewhat obscure, the early loss of voice and the frequent cough pointing rather to the lung than the liver as the seat of disease. In this connection it may be of some slight importance to note the demeanor of the patient, whose anxious look and depressed manner contrasted with the cheerful hopeful bearing so frequently seen in consumptives. The situation of the principal abscess cavities deserves special attention. When pus forms in the liver near the spine the diagnosis is almost certain to be embarrassed by the obscurity of the physical signs, and it may be also, as in my case, by the negative result of exploratory punctures. Before such an abscess can approach the surface of the body at any point easily reached by the surgeon, much liver tissue must be destroyed and the patient's strength greatly exhausted. Internal rupture is, however, the most likely termination of such a case. The question of the origin of a liver abscess seldom ad-

mits of definite settlement in individual examples, but I am myself inclined to accept Dr. Budd's theory of portal pyæmia as probably the true explanation of by far the greater number of those we see in the East. Diarrhoea or dysentery forms part of the history of nearly all these cases, but the absence of these symptoms should not lead to a hurried or incomplete examination of the lining of the bowel. My patient suffered from diarrhoea while he was under my care, and for more than a week before I saw him, but diarrhoea may also have been present at the beginning of his illness; for his memory of the earlier events was, he said, scarcely to be trusted. Ulcers of the bowel, if of small size may be overlooked even by expert and painstaking pathologists; how much more likely are they to be passed over in the examinations made by general practitioners, whose experience of practical pathology is usually so very limited. The ulcer which leads to the formation of an abscess may heal before the death of the patient. In the case at present under consideration, the open ulcers in the cæcum could not have escaped observation, but had it not been for the sub-peritoneal pigmentation, the cicatrix would certainly never have been noticed, and, for aught any one can tell to the contrary, that scar may have marked the site of the sore in which all the mischief originated.

Shanghai.

HEPATIC ABSCESS, TERMINATING FATALLY.

By Surgeon N. M. REID, A.M.D.

T. L.—, a private soldier, was admitted into the Military Hospital, Dover, on Aug. 5th, 1882, complaining of pain in the right hypochondrium, and slight cough. His previous history was that he had served ten years in India, where he had suffered frequently from ague, and twice from dysentery. He bore a good character, and was a moderate drinker. He stated that he had been on duty at Wimbledon during the early summer, and had since then been troubled with rheumatism in the right shoulder and side. His condition on admission was as follows. Spare but fairly muscular; skin and conjunctivæ clear; thorax well developed; respiratory movements ample, but attended with stich in the right side on deep inspiration; the lungs were resonant on percussion, expiratory sounds harsh, and at the end of a deep inspiration, at the base of the right lung in the mid-axillary line, there was a very faint friction-sound. The area of hepatic dulness was increased, the upper border corresponding to the fifth rib in the nipple-line, the lower border reaching about one inch and three-quarters below the ribs. The organ seemed uniformly enlarged, and, so far as could be ascertained by palpation, the enlargement was smooth on its surface, but there was much tenderness on even light pressure, more especially in the posterior axillary line. The spleen was also slightly enlarged, reaching about an inch below the ribs, but there was no tenderness of this organ, nor any along the course of the colon in the flanks. There appeared nothing wrong with the heart, except that the sounds were somewhat quick and feeble. Urine dark, sp. gr. 1016, acid; no albumen. The evening temperature registered 100.1°; morning 99°. He was ordered low diet, and a mixture of quinine, chloride of ammonium, and spirits of chloroform; two leeches over the liver followed by warm fomentations. After this, for a day or two, he improved somewhat; the pain and tenderness were less, but he had a sharp attack of diarrhoea. Motions dark, not peculiarly offensive; unattended with hæmor-

rhage or tenesmus; this was controlled by Dover's powders. At this period I was absent from duty for a fortnight, and on my return I found my patient much worse, suffering from severe cough, attended with abundant bloody expectoration, which, however, varied in appearance considerably, at one time being pneumonic in character, and a few days later being greenish, tenacious, slightly blood-tinged but not peculiarly offensive. The base of the right lung was dull on percussion, and there were abundant coarse crepitations audible both back and front. The left lung appeared quite healthy, save that the respiratory sounds were, as was to be expected, greatly aggravated. There was also again diarrhoea, and the temperature registered 103° at night. I was informed by the patient that during my absence he had one evening while stooping down suddenly brought up a quantity of blood, and "nasty tasting" stuff, which unfortunately was thrown away. I was now a little perplexed as to whether it was a bloodvessel which had given way in the lung, followed by secondary pneumonia, or an hepatic abscess which had ruptured and discharged through the air-passages. I came to the latter conclusion, taking into consideration his previous history, present condition, and onset of the disease; and was further of opinion from the obscurity of the local signs that the lesion was probably seated at the posterior part of the organ. The sputum was examined microscopically, but I could detect nothing definite, save pus and red blood-cells. From this point the patient, in spite of the most careful dieting and nursing, got gradually worse and worse. The diarrhoea proved most obstinate, and in spite of every remedy continued. The unfortunate man was reduced to a skeleton; eventually his motions were passed involuntarily, and his legs began to swell. He was evidently rapidly sinking, and died on Oct. 25th, just eighty-two days after admission.

The post-mortem showed great emaciation; almost total absence of subcutaneous fat; right lung adherent by recent and old adhesions to wall of chest; a large abscess the size of an orange at the base, communicating by an aperture the size of a threepenny bit, with a similar but larger cavity at the back part of the liver. Both these organs were studded with numerous other smaller abscesses. The gall-bladder was shrunken, and the bile watery. The left lung, save for slight hypostatic congestion, was healthy. There were three small abscesses in the spleen. The kidneys were pale and enlarged; slight reaction with iodine. About two ounces of greenish serum in the pericardium. The colon was thin; the mucous membrane raw-looking and ulcerated in patches.

Remarks.—In this case the remedies tried, especially with a view of controlling the diarrhoea, were numerous. Their effects were, unhappily, almost futile. They included opium, quinine, sulphuric acid, bismuth, ipecacuanha (small doses), fomentations, and inhalations. Stimulants were administered with caution at first; subsequently, their effect being beneficial, in larger doses. Surgeon-General Stewart, whose experience of these cases is large, advises the use of chloride of ammonium in hepatic derangements, which he considers to be almost a specific in uncomplicated idiopathic congestions and suppurations; but he states that its value in pyæmic cases is not nearly so great. In this case it was administered for three weeks systematically, but its effects were nugatory, as, indeed, was to be readily understood from the numerous attendant lesions and complications, sufficient causes for the non-efficacy of any drug, however valuable. Lastly, it is surprising to think that a patient could, as this man prior to his admit-

tance did, go about apparently in his usual state of health, except, perhaps, for slight fugitive pains, with few, if any, symptoms, and at the same time having a large abscess and such destructive changes going on in the liver. In such cases where the local signs are few, but where suppuration is suspected, I believe it will be generally seated at the back part of the organ.

ACUTE YELLOW ATROPHY OF THE LIVER.

By C. P. B. CLUBBE, L.R.C.P.L., M.R.C.S.

THIS case occurred lately in my practice. I regret that the clinical notes are not more complete. Had the nature of the case been recognized earlier, they would have been more carefully taken. I am indebted to Dr. H. Sainsbury, who saw the case with me a few hours before death, for his notes of the post-mortem which he kindly made for me, also for the description of the microscopical sections of the liver and kidneys which he prepared.

C. S.—, aged thirty-eight, a thick-set, well-nourished man, an iron-worker at a carriage factory, a very heavy drinker both of beer and spirits for twenty years, but for the last four months a teetotaler. On August 3rd, 1882, he was seen for the first time, when he came in the evening, having been at work all day, complaining of severe headache. Face pale; expression careworn; pulse frequent; constipated. Ordered a saline.—4th: Unable to get up; rigor during the night; pulse 90 to 100; temperature 105° ; headache very severe, avoids the light; chest and abdomen, physical signs nil; bowels well opened. Ordered two drachms of the solution of acetate of ammonia every four hours; ice-bag to be applied to the head.—5th: Headache less; feels better; conjunctivæ yellow; urine high-colored; pulse 94; temperature 102.5° .—6th: Rigors followed by sweats in the night; no headache; feels better; skin mahogany-color; stools pale; temperature 98.4° ; pulse 92.—7th: Rigors and sweats again in the night; jaundice more marked; slight pain, with swelling and redness of both wrists and some of the joints of the left hand; also pain in the elbows; complains of pain in the lower part of the abdomen. Physical signs nil; pulse 100; temperature 103° . Ordered five grains of the salicylate of soda every three hours.—8th: Rigors and sweats in the night. Wandered a little for the first time; rational now. Early in the morning the forearms began to swell, and became very painful. When seen in the middle of the day the patient was found to be in a state of collapse. Much jaundiced; great dyspnoea. Pulse 120, thready; temperature subnormal; respiration 40. Hands cold and bluish; both forearms much swollen, hard and tense, but not hot; skin dusky; superficial veins distended. On the inner side of the right arm there was a large patch of ecchymosis. Ordered brandy. 6 p.m.: Now evidently dying, all the symptoms worse. Still conscious, but wanders now and then. Ordered turpentine, ammonia, and ether. Never rallied. Died at 11 p.m. The patient passed but very little urine during the last twenty-four hours of his life.

Autopsy, forty hours after death.—Rigor mortis well marked; much post-mortem staining; jaundice well marked, but not intense; body well nourished; thick layer of adipose tissue. Thorax: Both lungs were congested posteriorly, but everywhere crepitant; some little emphysema in front. Heart: Pericardium contained some three ounces of bloody serum; no petechiæ on surface of heart; valves, especially the mitral, much stained, otherwise natural. Abdomen: On opening the abdo-

men, the liver edge was well above the costal margin. The liver weighed forty-eight ounces, very limp, thin, left lobe doubled up without the least resistance; the right lobe appeared, however, equally limp; texture softened somewhat; capsule stripped easily; on section lobules were distinguishable, but appeared less demarcated than normal. Spleen very soft and diffident; on section exuded a quantity of grumous fluid. Kidneys very soft and pulpy; capsule stripped readily; some ecchymoses on surface; on section small ecchymoses were seen in the cortex of the kidney. The bladder was empty. Stomach: In the lesser curvature there was a large patch of ecchymosis about the size of a hand. On cutting into the right arm, which was much swollen, thin, bloody serum exuded from the tissues. There was no collection of fluid, but a general infiltration. Sections of the liver under the microscope showed intense fatty degeneration, the cells being simply masses of fat granules, with no nuclei visible. In many parts the cells had broken down into a granular debris. Sections of the kidney showed decided cirrhosis, whilst the cells of the cortex were swollen, bile stained, and exceedingly granular (fatty).

Remarks.—Professor Thierfelder in vol. ix. of Ziemssen's *Cyclopædia of Medicine*, says: "Acute atrophy of the liver is one of the rarest diseases. . . . In its first stage the recognition in the present state of our experience is impossible." Of the 143 cases on which he bases his description of the disease, fifty-five were males and eighty-eight females; of these thirty were pregnant. Thirteen of the cases had been topers. On page 260, he says: "Fatty degeneration more or less advanced of the epithelium of the kidneys and of muscular tissue of the heart appears to be uniformly present. . . . Extravasations of blood occur in at least three-fourths of all cases, and commonly in several and very numerous parts of the body, and ecchymoses are observed in the intermuscular connective tissue, in and beneath the outer skin, in the mucous membrane of the stomach." There can, I think, be very little doubt that this was a case of yellow atrophy of the liver, for, as is shown above, the pathological changes were just those described by Thierfelder—viz., hæmorrhages into the intermuscular connective tissue, ecchymosis in the stomach, and the fatty degeneration of the renal epithelium. Then the liver both in its naked-eye and microscopical appearances was typical of yellow atrophy, as it is found described. The rapidly fatal termination probably accounts for its not being smaller. But its weight was only 1,357·8 grammes. Professor Thierfelder gives two cases, both topers, who died of yellow atrophy, where the livers weighed 1,520 and 2,100 grammes. The peculiarities of this case seem to be the rigors and sweats, with the up and down temperature, so pyæmic in character, and the swelling of the joints, such as occur in acute rheumatism and pyæmia. On this account alone the case may be of interest, but I am induced to send it for publication because it is an example of a rare disease.

Lower Tooting, S. W.

EXCISION OF STRUMOUS GLANDS.

By HENRY A. LEDIARD, F.R.C.S. Eng., M.D. Edin.,

Surgeon to the Cumberland Infirmary.

I HAVE had but two opportunities up to the present time of dealing with chronically enlarged, suppurating, or caseous glands in the neck in the above manner, but I am strengthened in the practice by what has appeared in print since I began this method by Billroth, who has had a very ex-

tensive experience, a record of which appears in a recent volume of the Sydenham Society's Transactions.

My first case occurred on Nov. 21st, 1881, at the Cumberland Infirmary, when a servant girl, of stalwart, robust appearance, presented herself with two large glands behind and below the angle of the jaw upon the right side. She scorned tincture of iodine, which had been used locally for four years, as well as iron and cod-liver oil. The glands were still enlarged, the skin unbroken, and no fluctuation present. There was no particular inconvenience felt, but the lumps were unsightly. She consented to have them removed, and this was effected through an incision of about two inches at the anterior border of the sterno-mastoid muscle. A gland having been exposed, I teased away the connective tissue around it with two dissecting forceps, and passed a thread through the gland, giving the loop to the house-surgeon to hold and draw the gland in suitable directions, continuing to tease the gland away from its bed. It was soon loosened and liberated without hæmorrhage, care being taken to seize with artery forceps the nutrient vessels passing into the gland. A second gland, below and deeper, was similarly treated, and the wound closed and treated with Listerian precautions. The glands were both of the size of large walnuts, and when cut into were firm, the centres showing patches of caseous change.

The second case (March 8th, 1882) was that of a very strumous-looking lad with a very large collection of glands stretching from the ear to the collar-bone on the left neck, together with a large abscess in the posterior triangle of the neck on the same side. I commenced by dealing with the abscess, which was opened antiseptically, and when the discharge had somewhat abated the glands were attacked as in the above case, but here the morbid changes were so advanced that two glands only could be pulled away intact, for the capsules of the others gave way, and the curdy, cheesy contents oozed out and were removed with a scoop. Gland after gland was reached, the capsule torn through and scraped out, until the space behind the sterno-mastoid and over the sheath of the carotid vessels was quite cleared out, almost a handful of the soft material being fished out, so to speak, with a scoop. Even then many small glands were left behind the ear and in the posterior triangle of the neck, but we were content with having broken up, evacuated, and obliterated some eight or nine without hæmorrhage. The immediate result as far as the size of the neck went was most remarkable, and the ultimate result, although not obtained by union by first intention, as in the previous case, was highly satisfactory. A counter opening had on two occasions to be made on account of discharge collecting at the bottom of the pouch cleared out, but with this exception and occasional pyrexial attacks, healing went on slowly and surely, the boy going to the Convalescent Hospital about six weeks after the operation.

From my limited experience I can point to this method as a safe and ready way to hasten the natural process of cure in such cases as the above, where glands are chronically enlarged, caseous or suppurating. Better results will be obtained where the glands are firm, for then the tumours can be fixed by a thread or otherwise, and dissection rendered easy. The knife is probably required to divide the skin only, fingers and forceps will do the remainder. In softened glands excision is impossible, but a tear in the capsule will admit a spoon like Volkmann's, and the contents of the capsule may be as easily scraped out as a boiled egg is eaten in its shell at the breakfast table. In

each case the patients were very satisfied with the result. Mary T—, the first case, even called at my house to thank me on March 23rd—i.e., four months after her operation, when nothing but a linear pink scar was visible. I venture to think that were this method generally adopted in suitable cases of chronically enlarged and caseating glands, fewer cases of disfiguring scars on the neck would be seen hereafter. Many women have lived to lament over large patches of cicatricial tissue in the neck and about the jaw. A linear scar, scarcely noticeable when whitened with age, would be infinitely preferable to my mind. Plenty of enlarged glands about the body yield to rest or medicinal and dietetic treatment, but these are not the cases at present under consideration. Billroth has operated ninety-four times; a great number of his operations have been very successful; some of them long and bloody; a few have proved fatal. I urge the use of two dissecting forceps, patient teasing, and the use of a spoon if necessary.

Carlisle.

SEVERE CASE OF COMPOUND COMMINUTED FRACTURE OF SKULL; RECOVERY.

By EDWARD HOSKINS, M.R.C.S.

On March 24th last a little boy, aged six years, was brought into my surgery suffering from severe injuries to his head. On inquiry as to the cause of the accident, I was informed that the child had been playing in a stable, and had fallen close to the heels of a cart-horse, which instantly lifted its foot and stamped, unfortunately, on the child's head.

On examining the wounds, I immediately perceived they were of a terrible nature, the left side of the head being crushed in. On the top of the head, extending from before backwards, was a lacerated wound three inches and a half long, bleeding profusely, and through which a large teaspoonful of brain escaped; here also were three large fragments almost detached from the left parietal bone. Over the left temporal bone, immediately above and behind the ear, was a swelling, and through the scalp, which at this part was uninjured, the bone was distinctly felt to be fractured, the sharp edge of the upper portion overlying the lower. On the right temple was a lacerated wound an inch and a half long, with a compound fracture of the bone beneath. Blood was escaping from the nose and mouth, and blood with brain substance from the left ear. The child was quite insensible, and appeared to be dying. After plugging and dressing the wounds, the fragments of bone were not removed. Perfect quiet for twenty-four hours was insisted upon, and small quantities of brandy-and-milk administered, though with great difficulty, at intervals. The radial pulse could not be felt, and the pupils were dilated. Twelve hours after the accident there was no change in the boy's condition, total unconsciousness remaining. At the end of twenty-four hours the pulse was just perceptible, and, as it was earnestly requested by the parents, permission was granted for his removal home, fresh dressings in the shape of lint soaked in cold water being previously applied; these were renewed every day for a week; each time there was an escape of brain from the large wound and ear. Altogether more than two ounces of brain substance were lost. The temperature ranged from 99° to 101°, and the pulse from 100 to 120. On the 27th slight consciousness returned, the patient opening his eyes when spoken to. At this time I perceived that there was total paralysis of the right side;

the urine passed involuntarily, and the bowels had to be relieved by enemata. On April 4th and on several subsequent occasions Dr. Gisborne, senior consulting surgeon to the Derbyshire General Infirmary, saw the child with me, and he regarded it as the most extraordinary case he had ever known. On May 19th, eight weeks after the accident the little patient was quickly getting well; the wound on the head was two inches long and one inch wide. There were two fragments of parietal bone projecting; these, though loose, were not removed at the time on account of the close proximity of the middle meningeal artery, which could be seen pulsating, and raising the pieces with each pulsation. There was great irregularity over the surface of the left temporal bone, which somewhat projected. The pupils were alike and contracted to light. The child sat up, and ate and slept well. The right leg had regained some power, and the arm a little; and although he could only repeat one or two words said to him, he looked fairly intelligent. On the 23rd one of the fragments was removed; it was diamond-shaped, measured an inch and a quarter in its greatest diameter, and weighed two scruples. On my visit on the 30th, I found the little fellow out playing in a field, the paralysis having almost entirely disappeared; his speech was better and in every way he was rapidly improving.

P.S. (July).—Since the above was written I have removed another large piece of the left parietal bone, and there is another portion which I shall take away in a few days. The child has gone on well throughout, has had no fit or any bad symptom. The paralysis of the right upper extremity has entirely disappeared; he drags the right leg slightly in running, but is daily acquiring more power in it. He articulates perfectly, plays in the park with his brothers and sisters; he eats, digests, and sleeps well, and appears quite well. The father of the boy keeps a lodge in the park of T. W. Evans, Esq., M.P. for South Derbyshire; and the kindness of that gentleman in supplying everything necessary, during the entire time, has had much to do with the child's recovery.

Duffield.

DEPRESSED AND COMMINUTED FRACTURE OF THE SKULL; RECOVERY.

By F. A. SAUNDERS, L.R.C.S., L.R.C.P. Ed., etc.

ANDREW S—, aged ten years, of Kingsbarns, Fifeshire, was, on September 1st, 1882, playing near a large farm cart, when the horse suddenly moved and the wheel crushed his head between it and the wall, which rendered him perfectly unconscious for a few minutes, but after his arrival at home he soon recovered consciousness. I saw the patient two hours after the injury, and found on examination, under chloroform, an incision extending from the left parietal eminence to the right superciliary ridges. The scalp was detached from its connections, and turned down over the left ear, leaving bare the left half of the cranium, and exposing a very considerable surface of bone. The periosteum was completely stripped off the frontal bone for the distance of three inches. The supra-orbital and frontal arteries were torn across and twisted; the left temporal muscle was torn from its connections with the bone and hanging loose, with the posterior temporal artery also torn and twisted. Upon reflecting the flap of skin back over the ear I felt and saw that the left parietal bone, one inch above the squamous suture was fractured, comminuted, and depressed, and a splinter of bone was easily detached. He was

then in bed, conscious but restless, moaning and suffering from great pain in the head. The pulse was quick (120); temperature 102.6°. The pupils dilated, but contracted slowly under the stimulus of light. Considering his age, and as there were no prominent symptoms of compression, having ligatured a branch of the anterior temporal artery that was bleeding I simply applied cold water cloths to the wound, and determined to wait before I brought the flaps of skin in contact. The next morning, September 2nd, I asked Dr. J. Moir, of St. Andrews, to see the case with me, which he kindly did. The temperature had fallen to 101.2°, the pulse to 108. He was quite conscious, and did not complain of much pain. We then determined not to trephine, but to follow out the expectant plan of treatment.

Dr. Moir having placed the patient under chloroform, I removed the greater portion of the temporal muscle and another small splinter of bone, and then brought the flaps of skin together as much as possible, taking care that perfect drainage was established. Ice was applied continuously for three weeks. During the first seven days the temperature oscillated between 101° and 102.8°. On the eighth day, when it rose to 103°, twenty grains of quinine were administered. On the ninth day the temperature was 103.4°, and twenty grains of quinine were again administered. On the tenth day the temperature was 104°; twenty grains of quinine given. On the eleventh day the temperature was 104.2°; the same quantity of quinine administered. On the twelfth day the temperature began to fall, going down to 102, and continued between 102° and 101° until Sept. 28th, when it kept at about 99° until Nov. 2nd. On that date I opened up a sinus by a two-inch incision, having felt dead bone, and removed three pieces of necrosed bone. The temperature then went up to 103° for two days, after which, in the following week, two similar pieces of bone came away. On Nov. 27th the wounds had healed sufficiently for me to leave the dressings to the care of the mother. The boy has done well since. The interesting features in this case are:—First, that although there was such a large surface of bone stripped of its periosteum there was no exfoliation; secondly, it is another example of Sir A. Cooper's, Abernethy's, and Dupuytren's advice, not to interfere unless there are marked symptoms of compression accompanying a depressed fracture.

Craik, Fifeshire.

ON TWO CASES OF TOBACCO AMBLYOPIA.

By THOMAS BUZZARD, M.D. Lond., F.R.C.P.,

Physician to the National Hospital for the Paralyzed and Epileptic.

FOUR years ago, A. B—, a gentleman, aged thirty-two, who had previously suffered from nervous symptoms associated with uric acid dyspepsia, complained that at a certain distance he could not see people's eyes, and that in reading he now and then lost sight of some of the characters. He came under the care of Mr. Brudenell Carter and myself. The patient was slightly myopic, and his unaided distant vision amounted to only eight-fiftieths of the normal; but was raised by a concave glass of one dioptré to eight-thirtieths. He had been feeling depressed and wanting in energy for some months. By the ophthalmoscope his discs appeared pale; but he is a dark-complexioned man, and it was doubtful how far the pallor might be apparent only, and due to contrast with the darkness of the fundus. His organs generally were healthy; the urine contained no albumen or

sugar, but abounded in urates. He had never had syphilis. The pupils contracted to light. On inquiry he complained of having suffered from sudden darts of pain in his arms and legs during the past winter. These pains sometimes lasted as long as a week, and then did not trouble him again for a month or so. His description fairly corresponded with that of the shooting pains of tabes of less than usual severity. The patellar-tendon reflex was found to be normal at each knee. In spite of this, his symptoms were so suggestive of incipient optic nerve atrophy of sclerosal character as to give rise to grave anxiety. His habit was to take about a pint of claret and three or four ounces of whisky in the twenty-four hours, and to smoke six or seven pipes of tobacco daily. His tobacco was cut down to one pipe a day, his alcoholic stimulant was reduced by half, and some strychnia was ordered. In one month the unaided distant vision had increased to eight-thirtieths, and was raised to eight-twenty-fifths by the same concave glass formerly used. In the hand, by the aid of a convex of one dioptré, the best he could do was to read 0.6 of Snellen's test types. The treatment was continued, and by the end of three months the distant (aided) vision of the left eye had increased to eight-sixteenths, while that of the left remained at eight-twenty-fifths; but Snellen's 0.5 could be read with either eye without the aid of a convex glass. The pallor of the optic disc was less conspicuous. The improvement has been maintained, and at the present time his sight is reported to be perfect.

In May, 1882, C. D—, a gentleman aged thirty-one, was attended by Mr. Carter and myself in consultation on account of amblyopia, which he had first noticed in the preceding March. The patient was a man of very active habits, leading a country life, but had been a somewhat free liver. He had never suffered from syphilis. The distant vision was eight-fortieths with either eye, and No. 3 of Jaeger's types could be read with difficulty by the aid of a convex one-fiftieth lens. The tension and color-sense were normal, and at that time there were no very manifest disc changes. The tongue was foul and loaded, but the organs generally were healthy, and the urine was free from albumen and from sugar. He was put upon iodide of potassium, with blue pill and compound rhubarb pill every night, and in a fortnight his condition had improved. The tongue was clean. He read No. 3 of Jaeger unaided, and the distant vision had increased to eight-thirtieths. The iodide was continued, and the pill given twice a week. In another fortnight there was a still further advance, the distant vision being eight-twenty-fifths, and No. 2 of Jaeger being read without assistance. At this point he remained stationary for a time, and then fell back, while at the same time the discs became pallid, and the sight of the left eye failed rapidly. He owned to some "rheumatic" pains at times, but at first said that he had never experienced any of a sharp and momentary character. Later he described having had a few attacks of this kind. The knee phenomenon was present on each side; but in August it was supposed (erroneously, I think) to be diminished, and at that time a very gloomy prognosis was entertained. We expected the knee phenomenon to disappear, and regarded the case as being probably one of tabes in which the optic nerve symptoms were dominant. Various treatment had been adopted without success, and for two months from August he took strychnia to the full production of physiological effects. At the end of this time the sight of the right eye remained much as it was when its acuteness was deliberately measured; but it had lost a little even in this re-

spect, and decidedly in quickness of perception, while the left eye had lost in acuteness to the extent of being practically useless, and its disc was much more pallid than formerly. Careful examination showed the knee phenomenon to be normal on each side. The patient had been advised in May to diminish his tobacco, but the advice had not been strongly pressed, and in October his acknowledged habit was to smoke ten or twelve times a day, pipes or cigars, but mostly the former, and to drink eight or ten glasses of beer, with a few glasses of wine, daily, and a couple of "grogs" at night. At this time, being then quite unable to read, he yielded to the advice given him, and left off smoking and "grogs," but continued to take eight glasses of beer and two of sherry daily. Arsenic and quinine were prescribed for him. At the end of three months he could read *The Times* comfortably, and had read a couple of books, but his optic discs continued very pale. Four months later he wrote: "You will be glad to hear that my sight since I last saw you has improved immensely. If not quite as good as ever it was, it is nearly so. I have, as instructed by you, left off smoking, except perhaps a cigar a month. I have also decreased the amount of alcohol; but I place the smoking as the principal cause. Although at one time I could not read the clearest type, I now read any book or newspaper apparently as well as ever I could."

These cases, and especially the second one, are calculated to support the view that changes in the appearance of the optic disc, closely resembling those dependent upon the atrophy so often associated with *tabes dorsalis* (locomotor ataxy), may have their origin in the excessive use of tobacco, excess being possibly measurable by the idiosyncrasy of the patient, rather than by the actual quantity consumed. In both instances, but most markedly in the first, the sudden pains which were described inclined us towards a diagnosis of sclerosal atrophy, and it was chiefly the continued presence of the patellar-tendon reflex which prevented the too confident expression of an unfavorable prognosis. In a case of optic nerve atrophy already published¹ no symptom of *tabes* has been associated with the intra-ocular change except that the knee phenomenon disappeared in succession from each leg while the patient was under observation. He is now irreparably blind.

Grosvenor-street, W.

A CASE OF GASTROSTOMY, FATAL ON THE TWENTY-THIRD DAY FROM ACUTE PAR-ENCHYMATOUS GASTRITIS.

By HERBERT W. PAGE, M.A., M.C. Cantab.,

Surgeon to St. Mary's Hospital.

THE operation of gastrostomy was undertaken in this case, in circumstances apparently most favorable, on account of impassable organic obstruction at the lower end of the oesophagus; and although the condition of the patient immediately and for three weeks after the operation gave every promise of success, death then took place from a sudden and acute attack of purulent inflammation of the walls of the stomach. The case is therefore a most important one, for apart altogether from the rarity of this form of gastritis, I am not aware of any instance in which a like unforeseen and unfortunate result has attended gastrostomy so long after all the risks of peritoneal inflammation have been avoided.

W. M.—, aged fifty-four, hitherto a perfectly healthy man, came under observation at St. Mary's Hospital in December last; complaining that for two months he had been getting weaker and thinner in consequence of difficulty in swallowing and the constant vomiting, or regurgitation, of his food. The man looked starved and ill. There was no sign of disease in any of his organs, nor any evidence of thoracic tumour, but a small bougie passed down the oesophagus was arrested at the cardiac end. The diagnosis was made of malignant oesophageal stricture, and he was accordingly taken into the hospital to be under closer observation, and that if it were found needful gastrostomy might be performed. He was an in-patient under the care of Dr. Sieveking from Dec. 9th to Jan. 12th; and although during this period the stricture remained as impermeable to bougie as before, he was certainly better able to take the food very carefully prepared for him, the sickness and regurgitation were controlled by a bismuth mixture, he gained five pounds in weight, and looked and felt decidedly stronger. He was enjoined to come back if he had any fresh trouble, and in a fortnight after his discharge he made his appearance again, all his old symptoms having recurred in a worse degree, and himself looking thoroughly exhausted and ill. It was resolved, therefore, that before opening the stomach some attempt should be made to restore his strength by careful feeding and nutrient enemata, and this had been so well accomplished by Feb. 21st, and the sickness now occurred so seldom, that the operation was performed on that day.

As to the operation itself there is but little to be said. Following the careful directions of Mr. Bryant, an oblique incision three inches long was made about three-quarters of an inch parallel to and below the margin of the left ribs, and ending opposite the tenth cartilage. The soft parts were divided down to, but not through, the peritoneum, and all oozing of blood was arrested. The peritoneum itself was opened for an inch, and the stomach, seen lying immediately beneath the incision, was seized and drawn out by a pair of forceps. By means of two loops of fine carbolized silk then inserted into the peritoneal covering, about one-third of an inch apart, the stomach was brought and held well forward through the wound, and was stitched by a dozen fine silk sutures passed just into the muscular coat to the divided edges of the parietal peritoneum. The operation was conducted under the carbolic spray, and presented only this difficulty or trouble, that in putting in the last—happily the last—suture, a vessel was wounded, and bled so persistently as to necessitate plugging the wound with a sponge before applying the dressings. In the after history there were few points of special moment. On the evening of the 22nd, the temperature rose to 100° F., but gradually sank thereafter to normal, and continued so until March 11th, with the exception of one day, Feb. 28th, when it rose to the same height in consequence of some slight parotid swelling from cold. The stomach was opened on the fifth day by a small incision with a tenotomy-knife, and great help in this second part of the operation was derived from the silk loops which had been left in the peritoneal coats. The opening in the stomach gave exit for two days to a profuse quantity of dark, greenish, sour fluid, but afterwards the escape of gastric juice was greatly lessened, although for a week the oozing was sufficient to cause a good deal of redness, swelling, and tenderness at the lower margin of the wound. This, however, was relieved by poulticing. He was fed by the fistula as soon as it was made, and from that time forward he was fed without the least

¹ Clinical Lectures on Diseases of the Nervous System, by Thomas Buzzard, M.D., p. 152. Churchill, 1882.

difficulty, and usually, though not always, without any regurgitation. By March 2nd all feeding by enemata, and by Slinger's nutrient suppositories, which had been found of the greatest service, was stopped, and he was so well as to be able to sit up in bed. His hunger was satisfied, he felt stronger every day, felt better in fact than he had done for some time before the operation, and was obviously gaining flesh. The wound was contracting naturally, he had not vomited since the operation, there was no indigestion, and the motions were well formed. By no possibility could he have been doing better, and it was hoped that in a few days he would be out of bed. But on the evening of March 11th his temperature rose to 101° F. without more obvious cause than constipation. It became normal again both night and morning until the evening of March 14th, when it rose to 101° F. He had been somewhat depressed all day, and that night he began to feel sick. He felt sick for several hours, and early on the morning of the 15th he began to vomit. The efforts at vomiting, for he brought up but little, were very violent, and afterwards he had intense pain. The vomiting ceased at 10 A.M., but the pain increased and was limited almost entirely to the region of his stomach, and here also there was un-doubted tenderness. From this time onward he rapidly failed, the pain increased, the temperature rose to 103° F., he passed into collapse and died on the afternoon of the 16th, thirty-six hours after he first began to feel sick, and after the temperature had begun to rise.

From the more extended post-mortem record of Mr. Silcock the following facts are taken:—"Eight and a half inches below the level of the cricoid cartilage was a hard white growth resembling scirrhous cancer, about the size of a chestnut, forming a ring around the œsophagus, and greatly constricting its lumen. The mucous membrane over it was eroded and ulcerated. The lymphatic glands adjacent thereto were enlarged. The edges of the gastrostomy wound, which had been made in the anterior wall of the stomach, appeared healthy; the peritoneal surfaces were in perfect coaptation, and the adhesions were firm and organized. About a pint of yellowish effusion, in consistence like melted butter, was found in the peritoneal cavity. No lymph was to be seen on the surface of the intestines, which were, however, greasy to the touch and injected, their coats being softened and easily lacerable. The only plastic deposits found were a few spots of lymph on the outer surface of the peritoneal coat of the spleen. A large quantity of gelatinous lymph was effused into the meshes of the subperitoneal tissues in the neighborhood of the stomach, especially around the œsophagus as high as the diaphragm, beneath the posterior layer of the small omentum, around the left kidney, and between the layers of the transverse meso-colon. The walls of the stomach were a third of an inch thick, and of an opaque yellowish-white color. This was most marked on the posterior surface in the neighborhood of the greater curvature, where it was in part obviously due to an effusion of lymph beneath the peritoneal coat. The mucous membrane of the stomach appeared to be swollen, and was of an opaque yellowish-white color, with here and there a few patches and streaks of injected venules. The surface was nowhere eroded or ulcerated, except at the margin of the wound, where it appeared to have undergone some slight digestion or softening. The thickening of the walls gradually shaded off towards the pyloric and cardiac ends, where it ceased almost abruptly. The coats of the first portion of the duodenum, however, were in some measure thickened. The cut surfaces of the stomach everywhere

exuded a creamy purulent fluid, which seemed to flow from the submucous and muscular coats, to the swelling and infiltration of which the thickening was mainly due. Except in one enlarged gland near the tumour no secondary deposits were found anywhere, and there was nothing specially noticeable about the other viscera. Microscopy showed that the tumour was a squamous epithelioma, and that one gland had been infected. The epithelial cells of the mucous membrane of the stomach were swollen and granular, were blocking the gland tubes, and had in part become disintegrated. The submucous tissues were infiltrated with inflammatory products, rendering them almost diffuent. The areolar meshes were crammed with leucocytes, and micrococci were abundant in the sections. The muscular coats were also swollen by reason of the inflammatory changes, but there was no lymph on the free surface of the peritoneal covering, although the peritoneum was inflamed and thickened. The mucous membrane at the margin of the wound showed no decided evidence of digestion, and was in much the same condition as the mucous membrane elsewhere, but not so markedly involved. The submucous coat was the seat of an intense inflammatory cell-proliferation, but not broken down, as was the case in other parts examined further from the wound."

Although there can be no doubt that it was from this remarkable purulent inflammation of the stomach that the patient died, it is not by any means so clear what cause gave rise to it. There was no phlegmonous condition or erysipelas about external parts, nor any evidence either from naked-eye or microscopical appearances that the inflammation started from the margins of the wound. The greatest care had been always taken to keep the opening sweet and clean, and although it was impossible after the second part of the operation, when feeding through the fistula began, to continue the Listerian dressings, neither cleanliness nor care had been abandoned. These facts notwithstanding, one cannot help fearing that the inflammation really began from the wound, and that in the absence of that wound the stomach would not have been attacked with this fatal gastritis. Recorded cases it is true lend little or no support to the septic origin of the inflammation, for in the majority of the cases where like appearances have been found, and where there was no evidence of general septicæmia, there had been no wound in the stomach, nor was any more certain cause discovered than excess in alcohol or deprivation of food. A very admirable account of this rare form of inflammation, which he calls "gastritis phlegmonosa," is given by Leube in Ziemssen's *Cyclopædia*,³ and he there describes exactly the same post-mortem appearances as were presented in this case. Scattered here and there in medical literature Leube has found thirty-one cases, twenty-six in men, five in women; but it cannot be said that his consideration of them throws any more light on the clinical features or the pathology of the affection than does the history of this one patient. Auvray records an example after stomach wound,⁴ but the most fully descriptive cases are those of Raynaud in a long paper on "Purulent Infiltration of the Walls of the Stomach."⁵ This form of gastritis is perhaps not so uncommon as the number of recorded cases seems to indicate, for it often happens that the stomach is passed over in post-mortem examinations. Be that as it may, the history of this case and operation deserves to be placed on record,

³ Vol. vii., H. 2, p. 43, Germ. edit.

⁴ Thèse, Paris, 1866.

⁵ Bulletin de la Société Anatomique, tom. vi., série 2, 1861.

pointing to an unforeseen and apparently unpreventable danger which patient and surgeon have to encounter after gastrostomy, even in cases where there is every promise of success, where the operation is undertaken before the recuperative powers have been altogether lost, where the risks of peritonitis have been safely avoided, and there is a hopeful prospect that life may be much prolonged, and death by slow starvation be prevented.

TWO CASES OF MALIGNANT (HÆMORRHAGIC) SCARLATINA TREATED BY CROTALUS.

By JOHN W. HAYWARD, M.D.

CASE 1.—Miss H.—, aged nine years, was apparently quite well on Oct. 5th, 1870; but in the evening she complained of sore-throat, with headache, chilliness, and dizziness. On examination the fauces and tonsils were found dark-red and cedematous. The only exposure that could be traced was that the cook in the house was laid up with diphtheria, and the only cause for that was that scarlatina was in the house of her family, and she had been there on Sunday ten days before. During the night the patient was very restless and feverish, and retched much and frequently, bringing up some dirty-looking mucus. At 8 o'clock next morning she was found to be extremely weak and very tremulous; her pulse was 160, very soft and small; the skin was hot, dry, and burning, with some brownish miliary rash on the chest; the tongue was furred, and the mouth dry; there was great thirst, but she drank only a little at a time, apparently because swallowing was very painful; the fauces and tonsils were mottled with rather bright red, and considerably swollen, as if with serous effusion into their structures, and there was a dark, dirty, sloughy patch on the left one. In consultation at 10 A.M. the case was diagnosed as malignant scarlatina of a very virulent type. During the day she grew steadily worse; the pulse increased in frequency and feebleness; great prostration and torpor supervened, so that she lay apparently unconscious, from which she was occasionally roused by retching of brown slimy mucus; the tonsils enlarged rapidly, making considerable fulness at the angles of the lower jaw, and causing the head to be thrown up and backwards; swallowing was extremely painful and difficult. In the evening of this day (Oct. 6th)—that is, about twenty-four hours after the beginning of the illness—she grew rapidly worse, and continued to grow worse in every way during the night; she was extremely restless, moaning and attempting to turn about, but was apparently too prostrate to do so, and the dirty mucus trickled from the mouth. On the morning of Oct. 7th, all the symptoms were still worse; the throat was nearly closed, and she breathed with difficulty, with an occasional interruption, as if from the swollen condition of the tonsils and fauces, which appeared softened, jelly-like, and as if gangrenous; the head was thrown upwards and backwards as far as possible; there was severe retching when anything was put into the mouth, even a teaspoonful of cold water provoked it, and the matter ejected consisted of dirty brown mucus, apparently colored with disorganized blood oozing from the mucous membrane, or resulting from the gangrenous state of the fauces and tonsils, and there were some bloody streaks as if from blood forced out by the act of retching. After the retching she would fall back on to the pillow, moaning in a very weak low voice, as if dying; and she sank down into the bed in a state of stupid lethargy, like a dying typhus patient. The breathing was irregu-

lar and jerky, sighing and intermittent; and there was loose tickling, almost incessant cough, as though from trickling of the discharges into the larynx; the pulse was scarcely to be felt; the rash was only faintly visible, and was brown and rough. It was now only about thirty-six hours since the beginning of the attack, but the case was apparently hopeless under the ordinary treatment. It was therefore determined to try the power of crotalus, which had been much recommended in the treatment of putrid and hæmorrhagic diseases, when introduced subcutaneously as well as by the mouth. The cuticle was consequently removed from round the throat by a cantharides blister, and to the exposed cutis a wet compress sprinkled with crotalus was applied, and renewed at first after half an hour and then every three hours, also a dose dissolved in a teaspoonful of water was dropped on the tongue every half hour. The effects were watched anxiously. There was no more retching after the first application of the crotalus to the denuded cutis, even when teaspoonfuls of beef-tea were put into the mouth; but the restlessness, pulse, and other symptoms continued much the same all the evening. During the night she gradually grew less distressed and dozed at intervals; towards morning she really slept, and the breathing gradually became less labored and irregular, and on being roused for some medicine, she opened her eyes, and, seeing her father at her bedside, exclaimed, "Oh, pa!" as if only just then realizing his presence. By eight o'clock in the morning of October 8th the pulse could be distinctly felt, and was only 120, the respiration was becoming easy, the head was less thrown back, and the struggle appeared to be turning in her favor. The rash was now freely out on the body and legs, but it was of a purple color. The same medicine was continued internally, but now only every two hours, and the crotalus was no longer sprinkled on the compress. During the day of October 8th the rash gradually brightened in color, and all the distressing symptoms receded rapidly, so that by evening she was able to drink with but little difficulty or pain; the respiration was almost normal and the pulse was 100, and had gained considerably in force and fullness. She slept well during the night, and the next day—that is, October 9th—her appetite began to return, and she looked wonderfully better, the change being really marvellous. From this date her recovery went on rapidly and steadily. The cuticle exfoliated rapidly, so that by the aid of vinegar baths and lard unguents the skin was about natural on October 14th. She was attacked on the 5th, nearly dead on the 7th, crotalus treatment was begun on the morning of the 7th, it rallied her almost immediately, and she recovered so rapidly that a very favorable prognosis was given on the 8th, and she was well on the 14th.

CASE 2.—J. D. H.—, aged thirteen, brother of the above, began to complain on the fifth day after his sister—that is, October 10th. His attack began in the morning and was marked by much the same symptoms as in his sister's case. There were great weakness, much dizziness, trembling, and staggering to falling before evening, and there were headache and nausea; the fauces and tonsils were dark red, and during the day they became tumid, and swallowing became difficult and painful. Pulse 130. He had a restless night, with increase of all the symptoms, especially those of the throat. The prostration was extreme, and on blowing the nose it bled freely. The next morning, Oct. 11th—that is, the morning of the second day of the attack—there was some brown miliary rash on the chest, and all the symptoms were worse. A blister was applied, and crotalus used as in the former case.

During the day there was much hæmorrhage from the nose, and reddish mucus hawked up from the throat. In the evening he appeared much the same and epistaxis returned twice during the night. The next morning, Oct. 12th, the rash was well out, and the throat symptoms were diminished; he improved during the day, and had some sleep during the night. Next morning it was evident that he was to recover. He made a like rapid progress as his sister, and was soon in fair health again. In this case, as in the former, cro-talus arrested the blood-poisoning at once, and turned the scale in favor of the patient within a few hours.

The above notes of these two interesting cases were written at the time, and have been preserved, and withheld from publication in order to test the drug in similar cases before publishing them. This has now been done over and over again, until the writer is thoroughly convinced that the above facts were no mere coincidences, and he now lays them before his colleagues in the hope that the drug will be used in similar cases, for which hitherto there has been no adequate remedy.

Liverpool.

SUBLINGUAL TUMOUR OCCUPYING THE LEFT SIDE OF THE MOUTH; IMMENSE SALIVARY CALCULUS REMOVED BY INCISION INTO THE GLAND.

By GEORGE MACKERN, M.D. Lond.

THE following case of tumour under the tongue is of interest, owing to the large size of the calculus which was found embedded in the substance of the sublingual gland.

James G—, an Irishman, aged fifty-one years, came complaining of a large swelling in the mouth, and of excruciating pain in the left ear and whole left side of the head. For several months he said he had noticed the swelling, but during the last few weeks only had he experienced difficulty in swallowing or speaking. During the last fortnight the pain had become so severe as to prevent his sleeping or resting in any way. On being questioned, he said that as long ago as ten years he had had occasional pricking pains in his mouth, and that off and on ever since he had been troubled with abnormal sensations in his tongue.

On examination, a tumour was seen occupying the space between the left outer border of the tongue and the left alveolar arch of the lower jaw; this tumour appeared to be about two inches long by one inch and a half broad, and extended from the frænum linguae in front outwards and backwards along the mucous membrane of the under surface of the tongue. In consistence it was hard and brawny, and the mucous membrane covering it was thrown into folds and had a peculiar livid look. In front, near the frænum, was a minute opening (the end of the salivary duct), and further back an ulcerated spot which, however, corresponded in position with a prominent molar tooth, from this ulcerated spot a few drops of pus exuded. Pressing the tumour backwards, and it moved easily as a whole, gave rise to great pain in the ear and left side of the head. Just below the jaw in the submaxillary triangle a small hard and painful swelling could be felt, this he said had only shown itself quite recently, and it appeared to be a secondary inflammatory product. The symptoms complained of were—pain and difficulty in speaking or moving the tongue; painful deglutition; dryness and soreness of the left side of the mouth; excessive pain of late in the left ear and left side of the head. I diagnosed an inflamed and

swollen sublingual gland due to obstruction of the duct (in the "remarks" will be found my reasons for this), and at once introduced a small probe into the minute opening near the frænum. The probe passed but a short way and apparently just under the mucous membrane merely; passing a bistoury in I slit the canal up along the probe, some drops of blood and some clear viscid saliva escaping. Carbolic solution was then injected and hot fomentations externally and internally were ordered, and the man told to come back in two days.

On seeing him again the surface of the tumour was less congested than before, and the pain had decreased a little. I now slowly and cautiously enlarged my first opening, going backwards and somewhat downwards into the very substance of the tumour. In a few moments my knife grated against something hard, and the nature of the case became evident. After a good deal of careful dissection a whitish calculus was laid bare at a depth of about half an inch. The anterior portion of the stone was very adherent, and had to be dissected out right round. With dressing forceps the stone was now easily lifted out of its bed, and the resulting cavity well syringed out with carbolic solution. Some blood mixed with salivary secretion escaped during the operation, but a little pressure easily stopped the bleeding. Afterwards some carbolized oil gauze was stuffed into the cavity, which was allowed in this way to heal up from below.

The growth removed is a hard, white, calcareous-looking mass, irregularly egg-shaped; the small end, which *in situ* was anterior, being quite pointed, very hard, and shiny, as if polished. The surface is rough, like morocco leather, but with bosses here and there. The stone measures an inch and one-third in length, two-thirds of an inch in width at its broadest part, and three-eighths of an inch in thickness; it weighs eighty-two grains (five grammes and a half). It can be scraped with a knife, but is not soft or friable. On touching it with strong nitric acid there is no effervescence, hence the surface at any rate does not consist of carbonate of lime; but the addition of the acid, however, brings out a strongly fetid odor. The chemical composition is not yet determined.

Remarks.—The diagnosis of cancer had been made by some other practitioners, but on careful examination it was evident that the tumour could not be cancerous, for these reasons—(1) The utter absence of anything like an infiltration of the surrounding tissues, the mucous membrane up to the very edge of the tumour being perfectly smooth and free; (2) the mobility of the tumour as a whole; (3) the long history of the case; (4) the fact that isolated cancer of the sublingual gland is unknown to occur, or is very rare. From rænula the tumour was easily distinguishable by its hardness, solidity, and general appearance and position. Some use was made of the presence of the swelling in the submaxillary region as an argument in favor of cancer, but from its extreme sensibility and its recent appearance I judged it to be inflammatory merely. On referring to the books at my command I find that the largest salivary calculus on record is figured in Bryant's Surgery, vol. i., p. 518, and that one weighed only forty-eight grains.

Note.—The operation was followed by a continual and troublesome discharge of thick saliva, which ceased on the third day, and was replaced by suppuration; the pus welled from below, and apparently was connected with the tumour in the submaxillary region, which for the next few days continued to be very painful and more swollen than before. On the eighth day the man was well, but in the submaxillary region there still remained

a small hard tumour like a marble; it was not painful, nor did it cause any inconvenience.

Buenos Ayres, South America.

ON A CASE OF MYXEDEMA, WITH REMARKS UPON THE ETIOLOGY OF THE DISEASE.

By J. OSWALD LANE, B.A., M.B. Cantab., etc.
House-Surgeon to the Northampton Infirmary.

M. R.—, aged forty-eight, attended this hospital as one of Dr. Buzzard's out-patients with the following history:—Father and mother died of old age; one brother alive and healthy. There is no evidence of a neuropathic predisposition, neither does she know of any relatives who have been affected with a similar complaint. She has had six children, the last one eight years ago, from which times she dates her present illness. She denies having been laid up with any previous illness, though for some time after each confinement she was accustomed to feel very weak and unable to do her work with her usual vigor. She had a particularly "bad time" at her last confinement, and has ever since suffered from weakness and debility. No syphilitic history; she remembers having been frightened before her last confinement, and has had a good deal of mental anxiety. She complains of having had a feeling of lassitude, weakness, and nervousness since the above mentioned date; at times has noticed giddiness, noises in the head, sparks in front of her eyes, with a feeling of pressure on vertex, disturbance of sleep, and loss of memory. Speech has become slower, with a pause between words. Walking slow and awkward; at times has fallen down. She has noticed the swelling of her face and hands only during the last six months, and she distinctly says that the nervous symptoms I have enumerated all preceded the latter. Has had sickness at times; has not passed much water.

When she first presented herself here her condition was as follows:—Her physiognomy on the first glance was that of a person suffering from renal dropsy; but on closer examination I found the oedema to be of a different character, in that it did not pit on pressure. The parts of the face most affected were the eyelids, lips, cheeks, and nose (the first two especially). The eyelids were pearly, semi-transparent, ridged, with drooping of the lower ones. The cheeks were puffy, so that the features were rounded in contour, with a circumscribed blush on both. The lips were pendulous, thick, and of a purplish tint. The nose was swollen, with dilated nostrils. The expression was stolid and sad, with a lack of mobility. The skin over the whole body was very dry and harsh; the patient said it had been "scaly at times." The hands were markedly swollen, so as to be of a "spade-like" appearance, and were clumsy, with a dilatation of the capillaries on the dorsal surface. The lower extremities were not swollen. The patient had lost much of her hair, while many of the teeth were decayed. She had a train of nervous symptoms, such as slowness of speech, which was deliberate, monotonous, of nasal tone, frequently swallowing before speaking. The patient's movements were slow, and her gait awkward, with a feeling of being about to fall. She complained of headache and giddiness, and her memory was decidedly faulty. There was diminution of tactile sensation, and the conduction of sensory impulses was markedly retarded. The muscles acted very feebly to faradization, and the reflexes were diminished, the patellar almost absent. She frequently feels chilly. There was no change in the thyroid glands. The

heart sounds were normal, and not accentuated; no physical signs of hypertrophy. The lungs were normal. The urine was examined every time she attended, and I was unable to detect even the slightest trace of albumen, though numerous tests were used. The temperature varied between 96° and 98°. The pulse was usually about 54, always slow. The ophthalmoscopic appearances were natural. The only drugs administered were iron, quinine, and strychnia.

I have published this case, first, as the patient seems to present most typically the symptom of myxedema; secondly, on account of the improvement the patient underwent during the four months she was under my observation, since at the end of that time her speech, gait, intelligence, and other nervous symptoms were decidedly improved, while the characteristic swelling had not made further progress; and, thirdly, the case is interesting on account of the absence of even a trace of albuminuria, or the presence of any other sign of nephritic disease.

I would now make a few remarks as to what seems to me to be the probable etiology of the disease. In several cases which I have seen there seems to me to be a striking resemblance in the symptoms of the disease to some of those frequently developed in some forms of lesion of the central nervous system, and my reasons for thinking so are that the characteristic nervous symptoms of the disease are particularly constant, and that they have become distinctly well marked before any signs of oedema has developed itself; in all the cases I have seen many nervous symptoms have been present, such as peculiar gait, slowness of speech, impaired sensation, subnormal reflexes, giddiness, impaired memory; furthermore, in three cases the disease has shown itself after some mental shock or anxiety; to this cause I would attribute the frequency of the disease in multiparae, as a rapid succession of pregnancies combined with mental anxiety would probably lead to exhaustion of the system, and especially the nervous one; in addition, many of the symptoms which present themselves are much allied to some of those observed in disseminated sclerosis and locomotor ataxy. The slowness of pulse and lowness of temperature are additional factors in aid of this hypothesis.

Northampton.

A CASE OF HEMIPARAPLEGIA SPINALIS;

WITH REMARKS ON MUSCULAR SENSE, ETC.

By JAMES MACKENZIE, M.D.

N. P.—, aged thirty-eight, a baker, when examined on Dec. 13th, 1880, complained of loss of power in the left leg, want of feeling in the right leg, and difficulty in evacuating his bladder and rectum.

History of the present attack.—In the month of June, 1880, the patient became conscious of an indefinite numb feeling at times creeping over the right leg. In the following month the sexual power disappeared, and a little later he began to experience a difficulty in voiding urine, till ultimately he could pass but a few drops. Catheterization having been resorted to, a large quantity of urine was drawn off. He himself used the catheter for three weeks, when a partial return of the bladder control caused him to desist. A difficulty in getting the bowels moved manifested itself at the same time, for which castor oil and injections were unavailingly tried. Obtaining no relief, he one day passed his finger into the bowel, and, slowly withdrawing it, the fæces followed. He

says there is a constant bearing-down sensation, as if the bowels required relieving, but without the above device this cannot be done. A month ago the left leg became weak, a symptom which has increased so that during the last ten days he has had to trail it behind him as he walked. His previous health has been good, and nothing of importance was elicited from an inquiry into his social condition and family history.

Present condition.—Patient is 5 ft. 7 in. in height, well built and muscular, and of fair complexion. The skin is moist and warm. Temperature is natural, no detectable elevation in either leg. There are two small cicatrices in the left groin, which he says followed upon a blow on the testicle twelve years ago. With apparent sincerity he denies the possibility of a chancre, though he admits having acquired a gonorrhoea about this period. I cannot detect any cicatrix on the penis. Of possible specific sequelæ there is only a statement of his hair falling off in considerable quantity some years ago. On the outer and upper part of the right leg there is a large red inflamed patch, six inches by three, with a blister the size of a florin in the centre. The patient was unaware of this condition till I called his attention to it. After conjecturing for a time what might be the cause, he remembered that while on a low stool, that morning, he discovered that his bare knee was almost touching the bars of the grate, in which a good fire was burning. From inquiry into the position and posture of the patient I had no doubt that this was the cause.

Nervous system; motor.—The patient as he lies in bed is generally raised to almost a sitting posture, with his legs laid straight out before him. The voluntary movements at all the joints of the left leg are weakly performed, and their extent limited. The voluntary movements on the right leg are strong and good. The patient with difficulty gets out of bed, having to assist the left leg in its progress with his hands. When standing he has to balance himself with the aid of convenient objects. He can walk, but does so trailing the left leg in the manner of an ordinary hemiplegic. Standing with his heels together he sways from side to side and before backwards, and ultimately falls, usually to the left side. During the time he is standing there is observed an ever-changing contraction and relaxation of the tendons of the right foot and leg as he attempts to steady himself. These movements are similar to those in the leg of a man who attempts to stand on that leg alone. There is no action whatever to be seen or felt in the tendons of the left leg. When he recovers himself from the inevitable stumble there follows a series of clonic contractions of the left quadriceps muscle. No motor abnormalities are observable in any other part of the body.

Sensory.—The patient complains of a numbness in the right leg and belly as high as the twelfth rib. On the left side all the cutaneous sensations are natural. Sense of touch on the right leg—he localized with considerable accuracy any spot touched. He is unable to distinguish two points applied at once, thinks there is but one, and indicates its site as some place between the two points. Even when the points are a foot distant, it is only after pressing hard and waiting some time that he becomes aware that there are two points being acted upon. Senses of pain and temperature are almost entirely abolished, as indicated by the above-mentioned burn, still he is vaguely conscious of these sensations when his mind is actively engaged in searching for them. These abnormalities extend all over the right leg, the right side of the abdomen to a short distance above the symphysis pubis, slanting upwards and outwards

to the level of the twelfth dorsal vertebra, but become less marked towards the upper portion. They are also limited to the right side of the scrotum and penis, the mucous membrane of the urethra as well as the skin exhibiting the diminished sensations.

Reflex.—(1) Skin: On tickling the sole of the left foot the movements consequent are exaggerated; right foot natural. (2) Tendinous: The patellar is very much exaggerated. It is not set up by striking the bones in the neighborhood, provided that the tissues connected with the tendon be not stretched by the blow. Slight reflexions also got in tibialis anticus, extensor pollicis, and extensor communis digitorum. Ankle clonus readily set up. The patient knows easily where his legs are placed. Examination of the spine and cranium reveals no abnormality. The special senses are quite normal, and the mental condition perfectly clear.

Genito-urinary system.—Micturates frequently, and with some difficulty. Since he has been able to pass water, and left off catheterizing, he has had to perform the act bending forward and straining hard. After he had evacuated the bladder to his own satisfaction, I detected by percussion that it was not empty, and on passing the catheter drew off several ounces of urine. He has no pain in this region, and the urine betrays no chemical or microscopical abnormality. The sexual functions still in abeyance.

Digestive system.—Tongue clean, and swallows well. Has a good appetite, and no discomfort after food. The bowels cannot be moved save by the afore-mentioned device. Purgatives he has taken in large quantities. On rectal examination with the finger, I found that the sphincter yielded more readily than natural.

Towards the end of January, 1881, the patient became worse. He then exhibited the phenomena of hyperæsthetic bands encircling the abdomen—the hyperæsthetic portion in the left side being broader and a little higher than that of the right. The bands could not be distinctly mapped out owing to the variability of the impressions produced. Thus, having enclosed in ink spaces where the patient declares he feels the pricking of a pin much less than natural, I proceeded to other places. On returning to the first spaces, I find from his starting and exclamations of pain that they have become hyperæsthetic. The dulled impressions are all either in the upper part of the hyperæsthetic area, or slightly above, where they occasionally intermit with the natural, about the level of the ninth rib on the left side, and the tenth on the right. I have been unable to map out the areas on account of the extreme variability of the impressions.

The sense of touch is all but gone, and in the right leg he can only tell that he is being touched provided that the object remains in contact with the skin for some little time. In like manner the other tests exhibit almost total abolition of sensation. The left leg exhibits a slight diminution of the sense of touch, but other sensations are quite natural. He is now unable to tell in what position his legs are placed, and is utterly at fault in discriminating between weights in both legs. The tendon-reflex is much exaggerated in both legs, more especially in the left. He is unable to walk, declaring that when he gets out of bed he does not know where his legs are, and is in constant danger of falling from the sudden uncontrollable jerkings of the left leg. Otherwise the voluntary power over the legs is in much the same condition as in the previous description. Percussion over the spine elicits symptoms of considerable tenderness over the eleventh and twelfth dorsal verte-

bræ and first lumbar vertebræ. Electrical stimulation with both currents reveals no abnormality in the muscular contraction. The sensation to this stimulation is absent in the right leg, but natural in the left. After this he was put upon antisyphilitic remedies, first the iodide of potassium, and afterwards a course of mercurials by inunction, till the physiological symptoms were developed. He gradually improved, and a year later his condition was as follows:—

Examined Feb. 25th, 1882.—His general health is very good, and he has latterly been increasing in weight. Circulatory and respiratory systems are healthy. *Nervous system.*—Motor: Voluntary power of executing movements at the joints of the left leg is small. Passive movements are resisted, more especially at the knee. The right leg is powerful, and under complete control, and passive movements unrestrained. In walking he trails the left leg. Sensory: Right leg always feels cold, and when he himself is cold he feels as if cold water were running down his right leg. The sensibility to simple touch, however lightly applied, is good on both sides, and he localizes accurately the spot touched. Tickling good on left; on the right diminished at the sole, and above the knee for some distance, and is nearly absent over the intermediate part of the leg. Pain natural in left leg; diminished and delayed on right. On both legs he can distinguish pinching from pricking. The sensibility to pain becomes about equal on both sides at the groin, but there is still a marked diminution of the sensibility on the right side of the penis and scrotum. He recognizes separate points to within three inches on the left leg, but they have to be many inches asunder before he can distinguish them on the right. Temperature: He is unable to distinguish cold test tubes from hot on the right leg, and the inability to distinguish extends as high as the level of the pelvic brim on the abdomen. Reflex.—Skin: On tickling left sole sensation is natural; muscular response diminished. Right sole movement natural; sensation diminished. Tendon: this is exaggerated on both sides; the tendons at the ankle are all susceptible, including the tibialis anticus; a few of these (tibialis anticus and extensor longus pollicis) contract on tapping the bones in the neighborhood. Sense of position: Is a little out of his reckoning with left leg, but accurate with the right. Weights: Very accurate with right leg; with the left leg he can discriminate between 1 lb. and 2 lb., and tell their relative weights, but 5 lb. he can scarcely lift, and thinks that there is about 20 lb. resisting him. Galvanism: Cutaneous sensation diminished in the right leg; muscles contract equally and naturally in both legs. There is no diminution in the bulk of the legs on comparing present measurements with those taken a year ago. Genito-urinary: There is considerable difficulty in micturating, and he accomplishes the act by two methods. In the one case he stands supported, stooping slightly forward, with the left leg thrown backwards and outwards. After a time a drop of urine escapes, followed soon by a few drops more, and latterly by a fair stream, but projected with little force. If he should talk during the act the flow stops, and he has to strain to get it to resume. He cannot tell when the stream stops or when it flows save by watching it. A few ounces are left in the bladder after the completion of the act by this method. In the other method he assumes a sitting posture, and passing his finger into the rectum there immediately ensues a full and forcible stream of urine. It generally stops soon after the finger is withdrawn, and is excited by its reintroduction. Neither by this method is he aware from

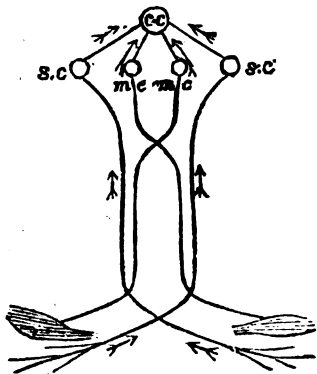

urethral sensations that he voids urine. In this way the bladder can be completely emptied. The power of coitus is still in abeyance. Digestive: Tongue clean; no discomfort after meals and appetite fair. The bowels are very costive, and he has to take castor oil frequently in order to get a liquid motion, otherwise the feces become hard and lodge in the rectum, whence they have to be displaced with the finger. On passing the finger into the rectum the sphincter is found laxer than natural, yet there is no incontinence.

The diagnosis in this case points to a syphilitic gummatous tumour situated either in the substance of, or in the sheath and pressing into, the left half of the spinal cord at the upper part of the lumbar enlargement. Latterly the gumma having in all likelihood been absorbed has left the tissues permanently damaged.

Brown-Séquard may now be considered to have fully established the method of recognizing a one-sided lesion of the cord by the very definite symptoms presented during life. The case I have detailed undoubtedly comes under the class of one-sided lesions, though, as in the matter of increased tendinous reflexions, there is probably some slight affection of the opposite side. I would more particularly direct attention to the muscular sense and the urinary and rectal reflexes, which present some features either at variance with, or not exhibited in, other cases; in part it may be due to the locality of the lesion.

Muscular sense.—Brown-Séquard, inferring from the cases studied by him, places the course of the muscular sense as accompanying the motor nerves. He has been implicitly followed in this statement by recent authors, as Erb, Ross, Gowers, Poincaré, Bramwell, etc. There is, to my mind, but a small portion of the truth contained in this statement, inasmuch as this sense is of a complex nature, and depends not upon afferent nerves alone for its transmission. By experience we learn to exercise a definite amount of muscular force in the accomplishment of any known act. When, therefore, we seek to raise with the hand any given weight, we are cognizant of the amount of nervous discharge employed to stimulate the muscle. The completion of the act or otherwise is made known to us by the afferent nerves, their terminations being affected by the change of position, etc. Thus in a case of hemianæsthesia, the hand of the affected side being held and the patient's eyes closed, if the patient be requested to put that hand to his head he will immediately put in action the required muscles, and be under the impression that the act has been accomplished, although the hand has been retained in its original position. Seeing that all sensation had disappeared on that side, the impression that the patient got was derived from experience, which taught him that the voluntary discharge of so much nervous energy was followed by a known result. So again with my patient. A few ounces on his leg did not obstruct its rising much, and the cutaneous sensation being intact he came to a fairly accurate conclusion. But when five pounds were placed on it, then he had to exercise more energy and strongly will a greater discharge, and the sensory nerves informing him that he failed to lift it he became confused, and attributed to the weight properties that experience had taught him to associate with this amount of nervous discharge. Thus, we have in the constitution of muscular sense two conditions affecting our consciousness—namely, motor feelings proper and sensation proper, as expressed by Professor Bain. The one is associated with energy passing outwards, the other with stimulation passing inwards; the two facts mingle together in the stream of mental life.

but are yet of a widely different nature.¹ This "motor feeling" is a sensation which accompanies muscular movement, "coinciding with the outgoing stream of nervous energy, and does not, as in the case of pure sensation, result from any influence passing inwards by incoming or sensitive nerves."² The parts constituting the muscular sense may be illustrated by the following diagram.

c.c. represents the centre of consciousness, being affected by the discharge, in obedience to the will, taking place at m.c., motor centre, on the one hand, and by peripheral stimulation passing upwards through s.c., sensory centre, on the other. Here, then, as I take it, the due appreciation of the part played by "motor feeling" is a result of experience. When any given act is to be performed, the amount of discharge of nervous energy is regulated according as experience has taught what amount of energy would overcome the resistance. Thus several weights externally similar are placed before me—say, five are of six pounds burden and one of one pound. In lifting each of the five I exert the same amount of force. When I come to the one pound, thinking it is equal in weight to the others, I consciously liberate the same amount of energy as before, and the sensory nerves inform me of the result, and by putting together the knowledge of the amount of the cerebral nervous discharge (motor feeling) and the sensory peripheral impressions, I come to a conclusion regarding the weights of the diverse bodies, the whole process constituting the muscular sense.

While this explanation accounts for the aberration of the muscular sense in the paralyzed limb, why has there not been noticed an interference with the sense in the limb when sensation alone was affected? The assumption of Brown-Séquard, and those who have followed him, that the muscular sense was conducted by motor paths, is militated against by analogy and several established facts. In the matter of analogy, it would require strong proofs to believe that motor paths convey sensory impressions. I will be content with quoting two instances in objection. The first is the case quoted by Sir Charles Bell and given by Brown-Séquard in his lectures, where in a typical spinal hemiplegic the muscular sense was undoubtedly gone on the side retaining muscular power, but profoundly anæsthetic. In a case quoted by Erb, abolition of sensation was accompanied with loss of muscular sense, yet retention of muscular power, when at the autopsy the motor paths were intact in the spinal cord.³ At one time

in my case, when there was profound anæsthesia, there was undoubted absence of muscular sense. Further, in most of the recorded cases anæsthesia has been said to exist when the patient failed to detect separate points within a certain distance; text-books give this as the method of testing the anæsthesia. I have made out clearly in my case that while the patient cannot tell that two points are touching him when from eight to twelve inches apart, thinking there is but one point, and that midway between them, yet the slightest touch with a fringe of cotton he immediately recognizes and accurately locates. I would be inclined to associate the conservation of the muscular sense with the retention of delicate touch and their simultaneous disappearance; and also that when there is retention of muscular sense in the non-paralyzed limb, the lesion does not entirely interfere with the functions, of the one side of the cord.

I would next call attention to the urinary and rectal conditions. I have not come across a parallel condition, and it may in a great measure be due to my patient being a man of resource. In the first described method the patient employs only the purely voluntary muscles in micturition. There is evidently a diminution of the peripheral stimulus reaching the reflex centre in the cord. This case, so far as pathological evidence affords proof for physiological conditions, certainly points in favor of the theory that the detrusor urinae is purely reflex in its function. To me the *rationale* of the process in this case is as follows: The patient feels slightly the call to micturate. He assumes a position which least obstructs the egress of urine. He strains and patiently empties the bladder. The detrusor does not act here, for, observe, the flow is weak and stops whenever he speaks. Now, when he alters his position by sitting on his haunches, opens his legs, passes his finger into the rectum, and thus sets up an additional stimulation (the vesical distension not being sufficiently strong in its stimulation of the reflex centre of the detrusor, owing to one-half of the nerves not reaching the centre), this rectal stimulation is sufficiently powerful to set up the contraction of the detrusor. Note his inability to tell from urethral insensibility that the urine flows. In this case the flow is strong, indicating the contraction of the detrusor. In like manner the rectum cannot naturally be emptied. It, like the detrusor, is only under reflex control. By exercise of the abdominal voluntary muscles substances lodged in the rectum cannot be voided, as found by experiment. So here there is also a diminution of the ordinary stimulation reaching the centre for the rectum. The patient therefore takes a purgative, and the liquid motion thus produced being more irritating, the deficiency in the stimulation is compensated, and the rectum reflexly contracts and expels its contents.

Burnley, Lancashire.

AN INTERESTING MIDWIFERY CASE.

By FRED C. CORY, M.D.

A SHORT record of the following complex case of midwifery may be interesting to the readers of THE LANCET.

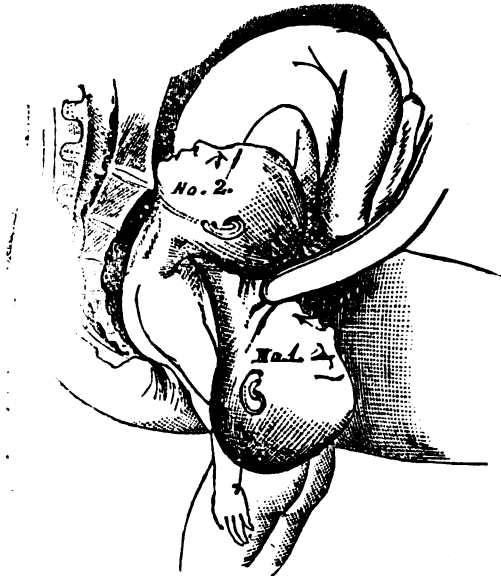

A poor woman (multipara), the wife of a mechanic, was being attended by an uncertificated midwife for two days prior to my seeing the case. I could not get from this woman any clear statement of how such a condition of things had taken place. She was confused in her mind, having a constant craving for stimulating her nerve centres,

¹ Senses and Intellect, 3rd edition, p. 74.

² Lib. cit., p. 77.

³ Ziemsscu's Encyclopædia, vol. xiii., p. 89.

which rendered her incapable of answering any questions, or even taking care of herself, much more of the patient. Of course this votary of Bacchus was very quickly dismissed from her post. The accompanying engraving presents a rough

sketch of the position of each child in and out of the uterus, as far as I could ascertain by their external appearances. These children were in a high state of hæmic congestion, amounting almost to blackness. The child whose head was expelled, and whom I shall for the sake of distinction call No. 1, had the face towards the maternal pubes, the chin resting thereon, with its neck pressed closely under the arch by the back and shoulders of No. 2; the body was above the brim. No. 2 had the body from the arms and shoulders downwards expelled; the chin of this child rested on the brim of the maternal pelvis by the right sacro-iliac synchondrosis, the occiput impinging on the upper edge of the pubis to the right of the symphysis. The greatest difficulty was experienced in getting the index-finger upwards, so that I could make out the different positions of the children. I think their relations to each other will be fairly represented in the rough drawing, although the neck of No. 2 was more elongated than is shown in the sketch. The woman was much exhausted by her long and continued efforts, begging to be helped out of her difficulty. I gave her some brandy with an egg well whipped up, which soon had the effect of improving her pulse, and cheering her with a few encouraging words of speedy help, for her spirits were much depressed by the midwife telling her she could not possibly live or get over it. I had great difficulty in introducing the perforator between the two bodies up to the occiput of No. 2, and perforating the head, when, by drawing down the shoulders during the come of a pain, the head passed into the cavity of the pelvis, and was soon expelled. The body of No. 1 quickly followed. The placenta was easily thrown off, and the uterus contracted well, there being little or no hæmorrhage. The poor woman was thus freed from her peril, and made a good recovery.

RUPTURE OF UTERUS CAUSED BY ASCITES OF FŒTUS.

SECONDARY HÆMORRHAGE ON FIFTH DAY; DEATH.

By A. CHEVALLIER PRESTON, M.R.C.S.

On Aug. 13th last I was sent for to attend Mrs. D—, aged thirty-five, a multipara, who was then, her friends said, in strong labour. Her previous confinements (six) had been normal ones, but I was consulted by her when seven months' pregnant with this child, about her unusual size. She complained at that time of entire inability to move about, and of a great sense of weight in the pelvis, far more than she had experienced in her previous pregnancies. I examined her then, and found nothing abnormal by vaginal examination, but the abdomen was stretched to an enormous size, and after careful examination I came to the conclusion that it was probably a case of excess of liquor amnii. I gave her a reassuring prognosis, as she was very nervous about herself, and I did not see her again until her confinement. I then found her in the first stage of labour, with the os dilating but slowly, and the head presenting in the first cranial position. The pains being infrequent, and there being no prospect of the case being over for some hours, I left her to go home for a short time. On my return in an hour and a half (3 p.m.) I found the pains had come on more frequently in my absence, and the os was dilating nicely, and half an hour after this was sufficiently so to admit the passage of the head. After waiting another half hour, during which the pains were very violent, and no progress was being made, I determined to rupture the membranes and apply the long forceps. I had an empty four-gallon pail placed under the nates at the edge of the bed, expecting an excess of liquor amnii, and I think the quantity that was evacuated could not have been short of three gallons, allowing for the soakage in the bedclothes, for the pail was considerably more than half filled. I then applied the long forceps without any difficulty, and commenced steady traction with the pains. I succeeded in delivering the head, and during this operation the woman did not complain of any extraordinary pain. I soon found, however, that on removing the forceps and applying traction to the head itself I could make no further progress, and after a few attempts I tried by grasping the uterus externally to excite contraction to bring the rest of the foetus into the world. After about ten minutes' waiting, during which time the woman had no pain, though I could feel pretty strong uterine contraction from external pressure, I determined to bring down the arms, thinking this might possibly be a case of obstruction from the shoulders, and with that object in view I passed my hand and brought down both arms and again made traction, but with no better success, and I knew then that the obstruction must be higher up. On passing my hand past the chest of the child, and on through the cervix uteri, I found an enormously distended abdomen, which I knew could not pass through the cervix. Finding this so, I passed a small pair of probe-pointed scissors (closed of course), which I happened to carry in my pocket, over my right hand, and perforated the child's abdomen as near to the umbilicus as I thought advisable, and a great quantity of serous fluid followed, similar in appearance to the liquor amnii. The patient meantime had a good pulse, with no complaint of exhaustion. Perceiving, however, that my difficulties were not yet over, and that the woman was becoming tired out, after another five minutes' delay, to see if the uterus would con-

tract strongly enough to terminate the labour, I made steady traction on the shoulders, with my fingers under the axillæ, expecting little if any resistance to the passage of a collapsed abdomen through the os. Such, however, was not the case, for in extracting the trunk I felt that something had "given way," as the woman herself cried out, and after separating the child (dead of course) as soon as possible, I passed my hand again, and found a large rent in the cervix, extending three or four inches towards the fundus. I at once detached the placenta without trouble, and finding the woman collapsed and almost pulseless, and tremendous hæmorrhage occurring, gave her a good dose of brandy and ergot, and grasped the uterus externally, and got pretty good contraction. The patient's pulse was meanwhile scarcely perceptible, and the respiration getting stertorous, extremities cold, and the face markedly cadaveric in expression. By dint of hot bottles to the feet, brandy and beef-tea per rectum, and a good firm binder and frequent hand pressure in the uterus, she managed to rally a little and to recognize those around her. I at once gave full doses of opium and ergot, to be repeated every two hours, and gave full instructions regarding the injections, etc. I left her for a little while, and later on met Dr. Nedwill in consultation, and we agreed to continue the above treatment, but he expressed his opinion that the case was then a hopeless one. This was at 3 A.M. on the 14th. She was not losing much blood, there was fair contraction, and the pulse was decidedly improving. We examined the body of the child there and then and found a markedly ascitic abdomen, which, when distended, must indeed have been enormous for a fetus in utero, and this evidently was the cause of the difficult labour. I saw the patient twice the next day, when reaction had set in. She expressed herself as feeling no pain. Pulse 140, weak; temperature 102.2°. Uterine contraction was good, and she could bear gentle hand pressure, but peritonitis was evidently impending, and in case she should be in much pain I ordered laudanum stupes to the abdomen if required. She was then taking a fair quantity of milk by the mouth, and I discontinued the rectal injections. I passed the catheter morning and evening, and continued the opium and smaller doses of ergot. During the three succeeding days peritonitis supervened, but the woman's general condition did not seem worse. Her pulse was on an average 130, and getting stronger, and she could pass water on the third day. I kept the bowels confined, and continued the opium and ergot. She still took a fair quantity of milk, but none was secreted by the breasts.

On Aug. 19th, five days after her confinement, I visited her in the morning, and found her still gradually improving. Pulse 110; temperature 100.2°. She was cheerful and in no pain, and taking food. Bowels still confined, as I wished to keep her as quiet as possible. I noticed that her aspect had much improved. At 5 P.M. I was hastily sent for and found that she had had a severe flooding in her sleep, and without any apparent exciting cause, for she had been kept perfectly quiet and had not been disturbed in any way. I found her literally saturated in blood, and the case had again assumed an alarming aspect. Collapse had again set in, with pulse almost imperceptible and cold extremities. I gave a dose of turpentine, applied a fresh binder, and stopped the hæmorrhage temporarily. Brandy and beef-tea were given per rectum again, but she died at 9 P.M. No post-mortem allowed.

Remarks.—This case appears to me an interesting one, from the fact of its uncommon occurrence, and from the fact of the patient living for five days

after rupture of the uterus. I am anxious to know if many similar cases have been met with, and what is the pathological connection between excess of liquor amnii and ascites of fetus. The immediate cause of death was, I believe, due to a large vessel in the ruptured cervix becoming unplugged spontaneously, but had not this happened, I see no reason why the woman should not have recovered. Had I eviscerated, the result would, I believe, have been the same, for it is my impression that the cervix gave way during the passage of the abdomen after the ascitic fluid was evacuated.

Lincoln, Canterbury, New Zealand.

A NEW METHOD OF APPLYING PRESSURE TO ENLARGED TESTICLES.

By J. L. CORBETT, M.D.,

Superintendent and Medical Officer, Lucknow Central Prison.

In the treatment of some of the diseases of the testicle accompanied with enlargement, the practice of applying pressure to the gland is undoubtedly a sound one, and is frequently resorted to by surgeons. I have often wondered that some simpler plan than that of strapping with plaster has not been suggested. The objections against the plaster strapping are numerous. First, it is a tedious business to do neatly and properly. Second, it is dirty both for operator and patient. Third, the operation has to be begun by encircling the neck of the gland with a long strip of plaster. This undoubtedly interferes with the free circulation in the vessels of the cord, and tends to prevent the absorption of the material deposited in the gland. It stands to reason that the freer the circulation in the vessels going to or from the testicle, the more rapid will the reduction in size be from the operation of absorption induced by pressure. Fourth, the strapping loosens very rapidly, and, to be of use, must be reapplied frequently. Fifth, in many cases, even when carefully applied, the plaster cuts the skin and leads to sores. Sixth, I have seen nasty troublesome eruptions on the skin of the scrotum following the use of the plaster.

I have, I think, enumerated enough objections to the old plan, and I will now try to explain the means I would recommend for obviating these objections, at the same time applying a steady, equable compressing force, and one which would also admit of easy regulation as regards the amount of compression. I may preface the explanation of my plan by saying that I derived the idea from a homely source, nothing more or less than seeing the means employed for encasing a football; barring, that instead of having the encasing material made of leather, I would have it made of india-rubber—such as one sees in the construction of the balls in spray producers, etc. The cases I recommend should be made of different sizes and thicknesses, oval in shape (same shape as the Rugby football when inflated). The means of tightening the cases and applying the pressure would be identically the same as in the football cover—i.e., by lacing. There should be an opening at the neck of the case to allow the passage of the cord. This opening would be surrounded by a ring (interrupted) of leaden wire, to ensure its patency and to prevent pressure on the structures of the cord. The leaden wire ring being interrupted, its softness would offer no obstacle to its easy adjustment round the neck of the enlarged gland. With a supply of the cases which I have attempted to describe above, the treatment of an enlarged testicle would offer but little difficulty; it would simply

mean the selection of a rubber-case of the right size and thickness, and capable when laced up of exercising a steady equable pressure on the enlarged organs, and applying the case to the testicle and lacing it up. If considered necessary, the testicle could first be enveloped in a thin layer of cotton-wool; this would prevent any possibility of the skin being nipped or chafed by the lacing. As the gland reduces in size a smaller case would be applied, and thus a steady pressure kept up until a cure was effected. The above plan has the advantage of simplicity, neatness, and quickness in its application to recommend it. It involves no elaborate apparatus, and I think does away with many, if not all, of the objections connected with the operation of strapping with plaster. I offer the suggestion in the hope that it may be tried by surgeons at home.

Lucknow.

CYSTOTOMY IN SUBACUTE CYSTITIS.

By GEORGE ELDER, M.D.,

Surgeon to the Hospital for Women, Nottingham.

THE chronicity and intractability to the usual methods of treatment of catarrhal cystitis, especially in the aged, is my excuse for placing on record the undermentioned case, illustrating, as it does, the strikingly successful result obtained by cystotomy and subsequent drainage when all other means, local and general, had been long and fairly tried. The patient was a woman aged seventy-two years, with a rheumatic history, who was admitted under me at the Women's Hospital on Dec. 12th, 1882. For months previously she had been under medical attendance at home, suffering similarly to what she complained of on admission. There was incontinence of urine, accompanied with frequent desire to micturate, vesical tenesmus, dysuria, and constant burning hypogastric and vulvar pain. The calls to urinate were so frequent that it was impossible to obtain a night's rest. The vulva and contiguous skin were excoriated, and the seat of intense pruritus. There was considerable constitutional disturbance and declension in health. The urine was rather scanty; specific gravity 1018; offensively ammoniacal, and depositing abundantly pus andropy mucus. Microscopic examination in addition showed the presence of pavement and cylindrical epithelium, a few fibrinous casts and phosphates.

Between December 12th and February 23rd all the ordinary medication, local and general, was tried, embracing rest in bed, hip baths, plain and medicated vesical injections, emptying the bladder at short intervals, alkalies, acids with and without sedatives, with the effect of relieving her distressed condition, but productive of no permanent improvement in the condition of the urine. Her general health also did not mend; so under either a vesico-vaginal fistula was produced on the latter-mentioned date, and a winged catheter attached to a long piece of rubber tubing inserted. The rest given to the inflamed viscus by drainage combined with injections, first of a solution of hyposulphite of soda, and afterwards dilute nitric acid combined with quinine internally, and acidulated drink *ad lib.*, soon effected a change for the better in her local condition. Speedy relief was given to the tenesmus, weight and local pains, and on April 28th it was noted that for three days the drainage-tube had not been in place, and the urine which could be retained from two to three hours was passed per urethram without discomfort. No urine came through the fistulous opening, and it was clear, faintly acid, and depositing only a slight

cloud of mucus. On May 9th she left the hospital entirely cured of her bladder troubles, passing painlessly perfectly healthy urine. The fistulous opening required no application beyond nitrate of silver. On May 31st the patient came to see me, and reported herself as able to retain her urine between three and four hours. The urine is normal and the fistulous opening closed.

Nottingham.

ACUTE RHEUMATISM AS A PREMONITORY SYMPTOM OF PHTHISIS.

By JOHN ALFRED AUSTIN, M.D.

RHEUMATIC fever has never been, as far as I am aware, put forward by any writer or observer as a premonitory symptom of phthisis. I have not even seen it mentioned, that an attack simulating acute rheumatism, and preceding the pulmonary symptoms, is occasionally observed as a phenomenon in the clinical history of that disease. Within the last few years, however, I have had under my observation no less than four cases of phthisis, in which the more decided pulmonary symptoms had been immediately preceded by the ordinary symptoms of acute rheumatism, where the lung disease seemed to have lain dormant, and to have been suddenly ushered into life and activity on the outbreak of the rheumatic attack. The swelling and redness of the joints and other symptoms, though not very severe, were sufficiently characteristic of rheumatic fever to prevent any error in diagnosis, and duly abated under the alkaline and opium or salicine treatment. The occurrence of four such cases in my practice within the space of three years entitles me, it must be allowed to a reasonable suspicion that there might be something more than chance in bringing about such a coincidence, that a rational explanation might yet be found for the curious fact, and that this might be classed among the many strange and capricious symptoms of phthisis, which often foreshadow with terrible certainty the advent of the dread disease. To understand and rightly interpret these omens is worth something to the practitioner, who has not only to anticipate the contingencies of each individual case that comes under his care, but has a reputation to maintain among his patients for far-sightedness and correct prognosis.

I will now briefly sketch the history of the cases referred to.

CASE 1.—L. M.—, a young girl, seventeen years of age, complained from time to time of severe rheumatic pains in the joints of the lower limbs. This is the only case in which redness and swelling of the affected joints were absent. After the pain had lasted a day or two, a copious eruption usually broke out all over the limbs, from the knees downwards, which had the effect of immediately relieving the pain. The eruption was a species of purpura—*peliosis rheumatica*. The attacks recurred from time to time, followed by more or less of the eruption, the relief from these attacks being always in proportion to the copiousness of the eruption. More than a year elapsed, and the girl was not thriving. The rheumatism to which she had been subject being hardly sufficient to account for the fact, I made repeated and careful examination of the chest, and eventually detected a small area of partially solidified lung in the left side. I expressed an opinion that one of the lungs was affected, and recommended the parents to give her cod-liver oil and iodide of iron. The idea of the lung being affected was such an unwelcome surprise to these people that they consulted another practitioner at once, who attributed matters

to delayed menstruation, and predicted a speedy return to health. Within eighteen months this poor girl died of phthisis.

CASE 2.—M. S.—, a tall strong-looking young woman, twenty years of age, general servant, consulted me for pain in her back. Suspecting it might have a uterine origin I made special investigation, but elicited nothing to confirm my suspicions, and came to the conclusion, somewhat reluctantly, that it was due to lumbago. A few days afterwards, however, this patient was prostrated on her bed with all the ordinary signs and symptoms of rheumatic fever—knees swollen, red, and painful, ankles and wrists also affected, and temperature increased. Under the administration of salicine these symptoms gradually subsided, and I discontinued my attendance. I had not thought of examining the chest. I heard nothing more of this patient for nearly two years, when I was informed that she was brought home from the South in the last stage of consumption. She died a few months after reaching home.

CASE 3.—C. M. L.—, a shepherd's daughter, aged twenty-one, was said to be ill with rheumatic fever. On arriving at the bedside of this patient I was on the alert to discover something more than rheumatism, and naturally directed a good deal of attention to the state of the lungs; and, as I feared, these organs showed signs of tubercular deposit. Under these circumstances I gave a guarded prognosis, informing the parents that the lungs, and not the joints, were the parts really affected, and that there was some cause for anxiety. It was a difficult matter for the parents, seeing the red and swollen state of the joints, to realize that they were not the sole cause of her trouble. But a few weeks after the abatement of the rheumatism the pulmonary symptoms showed themselves—when the racking cough, the purulent expectoration, and the rapid emaciation made it apparent to all that the poor creature was the subject of advanced phthisis.

CASE 4.—This case, also that of a young woman about twenty-four or twenty-five years of age, came under my notice only a few days ago. I was asked to see her, as she was said to be suffering from rheumatic fever. Her knees were much swollen and very painful. Temperature 101°. I directed special inquiries, with the view of eliciting any symptoms referable to lung disease. She said she had slight cough, but it was from cold contracted a day or two previously, and both she and the attendants repudiated the idea of lung disease, and manifested some impatience at my stethoscopic examination and questions about family history. Respiration was very weak, almost suppressed in parts, rough in others; creaking crepitation heard over both lungs. I prescribed for the rheumatic symptoms, and recommended the friends to administer cod-liver oil, expressing an opinion that her chest was weak. I left the house, wondering that with such a state of the lungs there had not been more decided symptoms. On calling, however, at the next house in that neighborhood, I was informed that this patient had recently had several severe attacks of hæmoptysis, which weakened her so much that her friends despaired of her life; a fact which they carefully concealed from me.

It will be noticed that all the subjects mentioned here were young females, whose ages ranged from seventeen to twenty-four. Another point worthy of note is the fatal nature of the cases in which this peculiarity was observed. Cases 1 and 2 proved fatal, Case 3 is utterly hopeless, and the prognosis in Case 4 is certainly not favorable; so that this premonitory symptom, if it be a premonitory symptom, must be looked upon

as one of grave significance. As for the *rationale* of these cases, I do not think we need go very far to find an explanation of the phenomenon. I venture to suggest that the synovial membranes may be affected to a certain degree by tubercular deposit sufficient to induce a passing inflammation of the joints, in the same manner as other serous and mucous membranes, and that acute rheumatism occurring coincidentally with phthisis must be regarded in the same class of complications as meningitis, peritonitis, and enteritis, occurring under the same conditions.

Tongue, Sutherlandshire, N.B.

ORCHITIS, WITH SLOUGH OF A PORTION OF THE TESTICLE, FOLLOWING TYPHOID FEVER.

By C. E. HARRISON, M.B. Lond., F.R.C.S.,

Surgeon, 2nd Battalion, Grenadier Guards.

Mr. X—, having passed through the fatigues and exposure of the recent campaign in Egypt, arrived at Cairo with his battalion on September 17th. On the 27th, having felt unwell for some days previously, he was seized with intense headache, high temperature, and other febrile symptoms, which, after running a somewhat irregular course, developed the characteristic features of typhoid fever. The rose-spots, the character of the dejections, condition of the tongue, enlargement of the spleen, and pulmonary congestion were all marked. On October 27th he was considered sufficiently convalescent, although still weak, to leave Cairo by river steamer for Alexandria, travelling thence to England in a hospital ship. There was some return of diarrhoea during the voyage home, and on his arrival in England on November 14th he was exposed to the cold east wind then prevailing. On the following day his temperature was 99.2°, and there was some looseness of the bowels. On the afternoon of the 16th he was suddenly seized with pain in the right testicle, which became very acute during the night. On the 17th I found the testicle considerably enlarged, with redness and œdema of the scrotum. The epididymis was but little affected. There was no gleet or history of urethral discharge, and no local injury could account for the acute orchitis. Considering his weak state of health, it was deemed inadvisable to abstract blood. Fomentations with poultices and extract of belladonna were applied, and a saline mixture, with an opiate at night, was ordered. On Nov. 18th the patient experienced considerable pain in the testicle, which came on in paroxysms. There was some fulness and tenderness in the line of the spermatic cord. Temperature 102.8°. On the 21st the temperature was 101.4°; pulse 96; slight shivering. On the 27th indistinct fluctuation was felt. Sir James Paget, who had seen the patient on the 21st, approved of an exploration being made with the needle of an hypodermic syringe, but the presence of pus was not detected. This is probably accounted for by the needle having passed into a portion of dead tissue which was subsequently thrown off as a slough. On Dec. 13th the fluctuation was distinct. Two incisions were made, but little pus was evacuated. On the 14th the temperature was 99°. A small portion of slough presented between the edges of the upper wound, and this continued to increase in size, being gradually extruded. Having reached the size of an almond, the slough finally came away at the end of the month, and the wounds completely healed. At the present time the testicle is considerably diminished in size, but no further trouble has resulted.

To those interested in this rare sequela of typhoid fever, an interesting paper by M. Vidal, and a discussion on the subject will be found in the "Bulletin de la Société Clin. de Paris," 1877-78, p. 142. M. Dieulafoy here mentions that he has seen a case of suppuration, and that M. Chedevergue has reported another. Various causes to account for the complication are here suggested. M. Vallin suggests catarrhal inflammation of the seminiferous ducts; M. Vidal, thrombosis of the spermatic veins; M. Hallopeau, parenchymatous lesion rendering the organ susceptible of injury. In the same volume, p. 229, M. Sabourin reports a case. In the "Archives Générales de Médecine," 1878, vol. ii., p. 595, M. Hanot reports several cases, one case being almost identical with the subject of the present report. M. Paul Larquier published a thesis in 1882, entitled "L'Orchite dans la Fièvre Typhoïde." Dr. Marston in his excellent paper on the fevers of Malta and the Mediterranean in the reports of the Army Medical Department, 1861, speaks of rheumatic orchitis as occurring after the Mediterranean remittent fever. He mentions one case of suppuration. Dr. Duffey's paper (in the *Dublin Journal*, 1872, vol. i., p. 97) was referred to in a recent issue of THE LANCET. Prof. A. Liebermeister, in Ziemssen's *Cyclopædia*, vol. i., p. 181, speaks of the complication, but observes, "All the cases that I ever saw ran a very slight course." As to the cause, may not orchitis be closely allied to parotitis, which is also a sequela of typhoid, and may not both be described as an expression of blood-poisoning?

Wellington Barracks.

A NOTE ON THE PRACTICE OF SURGERY.

By WILLIAM S. SAVORY, F.R.S.,
Surgeon to St. Bartholomew's Hospital.

THE observation that doctors are too prone to act upon insufficient evidence is a very old and familiar one, and from time immemorial it has been the occasion of much wit and satire. The attempts which so often have been, and still are, made to establish some principle of treatment or mode of practice on inadequate grounds is, of course, to some extent natural and perhaps inevitable. The enthusiasm of inquiry, the force of impressive facts recently witnessed, go far to explain it; but withal, when carried, as perhaps it too frequently is, to an extreme point, it is apt to produce much mischief, to say nothing of discredit. Single cases, for instance, are not unfrequently quoted in this way, as if they could prove or show that the result which they illustrate is the usual or probable one. A consultation is held on the treatment of some obscure case; an important measure, such as an operation of very doubtful prospect, is proposed; an objection is taken to it on the score that it will probably fail or prove fatal; then immediately some one tells of some single case in which he was concerned when it turned out to be successful. Now if such a single instance be only used to show that the operation in question is practicable, that it may be successful, that it is possible for it to answer the desired end, well and good; or if it be used in illustration of the argument, no reasonable objection can be raised against it. But what further use ought to be made of it? If it be the sole instance in which such an operation has been performed, then of course it stands alone, and must be taken for what it is worth. But if it be only one case out of many, or even of a few similar ones, it is clear that its value in the question can be adequately measured only

when it is taken in conjunction with the rest. A and B are considering the question of an operation on C. A urges it because he has had one or two or three successful cases of the kind. But supposing A or B knows of twice or thrice as many others which have proved fatal or otherwise disastrous, how then does the evidence in reference to the operation before them stand? Surely we sin too often against reason in this way. Who cannot recall too many instances? It is, of course, clear that mistakes from this cause may arise in either direction, in the way of action or inaction; but who that has had much experience can doubt in which direction the greatest danger lies.

Closely connected with this carelessness of thought is a certain looseness of expression with regard to the result of particular operations. When an operation is said to be successful, what is to be understood? Surely it should mean that the end for which the operation has been performed has been accomplished. There must be a purpose in every operation, and unless it has been reached the operation must have failed. But how often is the term "success" applied to recovery only from the injury inflicted by the operation itself without reference to the object for which it was undertaken or knowledge of the result. If an operation be performed solely for the purpose of saving life which, but for such timely help, would have been forthwith sacrificed, then, indeed, recovery from the operation itself is fairly entitled to be called success; but if an operation be performed for the repair of some defect or the correction of some deformity, or with the object of removing some hindrance to the action of a part or of increasing its usefulness, then, although the person may recover rapidly from the operation itself, unless such end be gained it must be pronounced a failure; nay, even if an evil be removed, and another equally grave be established in its place, the term "successful" cannot fairly be applied to the operation. In some cases many weeks or months must necessarily elapse before it can be seen whether the purpose of the operation has been attained, and yet how many cases have been recorded as successful long before the period has arrived at which the question could be fairly answered. For example, an operation is performed for the removal of some hindrance to the strength or activity of a limb. As soon as the patient has recovered from the operation the case is published, or at all events from that date no further information is given or perhaps obtained of the result; yet clearly the chief fact which requires to be ascertained is the condition of the limb at a remote period. If the operation be really successful, by the omission of such knowledge an injustice is done to it. If it be not successful, then by such silence an injustice is done to surgery.

Again, I cannot help thinking that the practice is, in some instances, too common of throwing the responsibility of an operation upon the patient. Surgeons perhaps are sometimes too prone, as the result of deliberation, to declare, Well, I will put the matter before the patient and leave him to decide. Now it strikes me that this can hardly ever be quite right. As Sir James Paget has said, "As to the amount of good which is to follow an operation the surgeon alone can in most cases estimate it. In most cases therefore we must take the whole responsibility of operation, for it is only on our statements that patients can rely in judging whether they should submit or not; and most of them, even when they have our statements before them, are quite incapable of clearly and soundly judging." And not only so, but too often it is in proportion to the degree of doubt in

the surgeon's own mind that he becomes anxious to shift the responsibility. When the case is clear to him he expresses a positive opinion, but when the advantages and objections are more equally balanced he attempts to place them before the patient and to leave the issue to him. It is therefore in cases in which decision is most difficult that the patient is called on to decide. This ought not to be. Sir James Paget would make an exception in cases of what he wittily calls "decorative surgery." But I confess it seems to me that even this exception should be admitted only with considerable qualification. For when a man or woman is promised a better appearance as the result of an operation, how can either judge of its degree? When, for example, a surgeon proposes to make a new nose, can the patient picture at all adequately the new feature? And yet this is a point of the highest importance in coming to a decision between a new organ of flesh and an artificial one. I think that whenever the surgeon places the whole case fully and fairly before the patient he should at least never withhold his own opinion; and the instances ought surely to be very exceptional indeed in which he should act in opposition to it.

STEWED FRUIT FOR THE GOUTY AND THE DYSPEPTIC.

By J. MILNER FOTHERGILL, M.D.,

Physician to the City of London Hospital for Diseases of the Chest, Victoria Park.

PROBABLY the impression first created by scanning the title of this paper will be as follows:—"Why, what have either the gouty or the dyspeptic to do with stewed fruit at all?" That sugar is apt to disagree with sundry stomachs, causing great acidity, is a clinical fact not to be disputed. But because such is the case with a limited number of persons it does not seem, to me at least, that therefore a sweeping prohibitory law is to be laid down for a large section of the community. Gout poison, all admit, is a product derived from the albuminous constituents of our food, as nitrogen is a marked element in its composition. It is, then, the albuminous element in our food which has to be avoided in lithiasis. How sugar, fruits, and even vegetables came to be banned my researches have not enabled me to ascertain. From the time of Magendie's path-breaking essay writers on gout have advised the restriction of the nitrogenized, or azotized, constituents of our food in cases of lithiasis. But that the objection to sugar in gouty cases exists may not be denied. In speaking of stewed fruit for the gouty and the dyspeptic my views will be heterodox in the eyes of many. But neither the light of chemistry nor the lessons of practice conflict with my views. I am quite prepared to undergo any criticism these views may elicit or provoke. Indeed, the subject would be all the better for being thoroughly ventilated.

At the outset, I admit that for many persons—gouty, dyspeptic, and glycosuric—ordinary stewed fruit is objectionable from the amount of added sugar it contains. Where the acidity of fruit is masked or hidden by an excess of sugar, then the resultant product is cloying to many palates, and offensive to many stomachs. Probably in this all readers will agree with me. But it is by no means necessary to render stewed fruit objectionable by adding much sugar to it. Deprived of this excess of added sugar, stewed fruit can not only be rendered unobjectionable, but be converted into an

actual prophylactic measure, especially in cases of lithiasis. In order to attain this end all that need be done is to neutralize the excessive acidity by an alkali, and then little or no sugar is required. Thrifty housewives have long been familiar with the fact that the addition of a small quantity of the bicarbonate of soda to stewed fruit reduced the acidity, so as to save the necessity for much sugar. This was done simply for economy. The principle has a far wider application. Last June I was requested to visit a lunatic in the Midlands who was also gouty; and when the gout was acutely present she was more excitable and violent than usual. No medicine would she take, but she was very fond of stewed fruit. To add potash to her stewed fruit was very easy, yet very effectual. After this I gave my cook instructions to perform a series of experiments for me with all our ordinary native fruits. The result of this was that the amount of bicarbonate of potash required for each pound of fruit was found to be about as much as would lie upon a shilling. And this is a much better guide for a cook than to put so many grains. With all fairly ripe fruit this was just sufficient to neutralize the acidity, and bring out the natural sweetness; indeed the resultant product was quite sweet enough for most adult palates. Such stewed fruit could be eaten alone, or with milk puddings, or with cream, or the Swiss milk in bottles. Gooseberries, currants of all kinds, apples, and plums, all alike were excellent when so prepared. There are some points, however, to be attended to in practice, which are of more or less importance. The first matter is this: with dark fruits, as the black plum for instance, the color is impaired by the alkali, and the fruit is less attractive to the eye than is that of the ordinary stewed fruit, which is of a deep clear crimson. This matter is easily got over: a little cochineal will give the desired color. Another is this: where there is no natural sweetness to neutralize the acid completely by an alkali leaves nothing, simply a cold mass, to which the palate is absolutely indifferent. Such is the case with rhubarb. Here it is well to use half or all the amount of alkali with some sugar. The same is the case with early gooseberries before they have any natural sweetness; no sugar formed in them. Here the full quantity of alkali should be used, and the remaining acidity met by sugar. When three-quarters of a pound of sugar is required to sweeten one pound of fruit, only one-quarter of a pound of sugar is necessary after the alkali has been added. The sour-sweet taste is thus secured, which is toothsome. Now, in these two instances the stewed fruit is only rendered less objectionable to the stomach plagued with acidity, not made quite inoffensive. But for ordinary gouty individuals not troubled with acidity of the stomach, such stewed fruit is quite admissible, and forms a pleasant method of taking potash. The whole subject is one which deserves attention from invalids as well as their medical attendants, as it opens up to many a new field of diet altogether. Fruits *au naturel*—as the strawberry, for instance—are good in gout from the salts they contain, and are unobjectionable stewed, if it were not for the acetous fermentation of the added sugar. Here soda may be used. But where there is lithiasis the alkali ought to be potash. The gouty and the bilious alike are troubled with the products of the metamorphosis of albuminoids. Neither the lithates of the gouty nor the bile acids of the bilious are derived from the saccharine or farinaceous elements of the food. It was possible to make bricks without straw, but it is impossible to make bricks without clay! No liver can make these nitrogenized substances from simple hydro-carbons; it is physically impossible! The dietary for each is

the same—a non-nitrogenized dietary, in which vegetables and farinaceous matters are indicated, and saccharine matters, too, unless acidity in the stomach is produced by them. Milk puddings and stewed fruit are excellent for the dyspeptic, the bilious, and the gouty, as my experience tells me; and for one of those who suffers from taking sugar nineteen would be all the better for stewed fruit. But for those who dislike sweets, and for those who suffer from acidity, it is well to prepare the stewed fruit with alkalies, completely and solely or partially, as the case may be. This may sound very heterodox to some readers; but just let the incredulous test the matter for themselves.

Now, there are two other matters remaining to be alluded to, on which it is impossible to speak dogmatically, or *ex cathedra*; they are, rather, matters of personal belief, and they are these:—1. It does not seem a matter of indifference in lithiasis what forms of albuminoids are taken. The flesh of animals is rather converted into peptones by pepsin in an acid medium—that is, by gastric digestion—than by trypsin in an alkaline medium. And such peptones seem specially liable to form lithates. Caseine is more specially digested by trypsin in the intestine, and such caseine peptones seem less readily converted into lithates; the clinical fact being that a milk dietary or a pulse dietary is good for the subjects of lithiasis. Caseine is the form of albuminoid it seems to me, best suited to the gouty. Milk or milk puddings (made without eggs) are capital food for the cholæmic or the lithæmic. These fibrin-albuminoids, digested by pepsin, are laxative, while caseine is binding or constipating.

Milk puddings, then, go well with stewed fruit, which is a laxative. Many thoughtful physicians agree with me in the above matter. Now I am approaching what some may hold very disputable ground, yet nevertheless I venture to say here what I am beginning to think. Both for the classical diabetic and the glycosuric, cane sugar—the sugar of commerce—is bad, producing the unpleasant symptoms of sugar in the blood very readily. Yet many glycosuric individuals can take farinaceous matter with comparative immunity from discomfort. Starch in its way to grape-sugar is much less troublesome than is cane-sugar passing into grape-sugar, why I do not know, but the fact remains. Now, with many glycosuric individuals fruit stewed in the manner advocated here is quite permissible, while ordinary stewed fruit is very objectionable. For the dyspeptic, the gouty, the bilious, and the glycosuric individual (as well as the truly rheumatic, a small class), fruit stewed with an alkali in the proportion of as much bicarbonate of soda as will lie upon a shilling to the pound of fruit, when put in the oven, will be found both palatable and permissible. It saves the gastric acidity from the acetous fermentation of the sugar in the dyspeptic, or with the glycosuric relieves him from the excess of cane-sugar which disagrees with him. Where there is distinct gout not only is fruit stewed with an alkali good and unobjectionable; but if it be prepared with the bicarbonate of potash, it is converted into a therapeutic agent of no mean value; while the resultant product is quite sweet enough for a palate which has outlived the “sweet-tooth” period. The whole matter is a simple one, yet it seems to contain much promise for many persons.

Park-street, W.

— At a recent meeting of the Society of Physicians of Vienna, Dr. Felix Schwarz exhibited a man the subject of wandering liver. Needless to say, the case excited great interest.

Nulla autem est alia pro certo noscendia, nisi quamplurimas et morborum et dissectionum historias, tum aliorum tum proprias collectas habere, et inter se comparare.—MORGAGNI *De Sed. et Caus. Morb.*, lib. iv. Proœmium.

UNIVERSITY COLLEGE HOSPITAL.

CASES OF PSEUDO-MEMBRANOUS (DIPHTHERITIC) OPHTHALMIA IN NEWLY BORN INFANTS, SIMULATING ORDINARY PURULENT OPHTHALMIA.

(Under the care of Mr. TWEEDY.)

DURING the last two years about a dozen cases have been presented at Mr. Tweedy's *clinique*, which on casual inspection seemed to be ordinary purulent ophthalmia of infants, but which on closer investigation proved to be allied to genuine diphtheritic ophthalmia. In several of these the first peculiarity to attract notice was the disproportion between the degree of corneal complication and the amount of conjunctival inflammation. Inquiry usually elicited the fact that the affection of lids did not begin till a week or more after birth, and that for the first few days the inflammation was apparently not severe nor accompanied with much discharge. An examination of the conjunctiva lining the lids disclosed the presence of more or less adherent and semi-infiltrated pseudo-membranes.

The following case, for the notes of which we are indebted to Mr. W. D. Halliburton, M.B.C.S., ophthalmic assistant, is given as a mild but typical specimen.

Diphtheritic Conjunctivitis in an Infant four weeks old; Quinine Lotion; Recovery.—John G—, aged four weeks, was brought to the ophthalmic outpatient department on February 12th last, affected with great swelling of the right eyelids accompanied with purulent discharge. On Feb. 9th (three days before the visit) the swelling of the lids first appeared, and continued to increase. At the time of admission both lids were very much swollen, tense, and oedematous. The palpebral conjunctiva was smooth, rather pale, and covered with a thin semi-adherent pseudo-membrane. This was detached with a little difficulty, and exposed a smooth and pallid mucous membrane. The cornea was clear and the left eye was unaffected. The case was looked upon as one of diphtheritic ophthalmia, though no history of diphtheria could be made out either as existing in the family or in the neighborhood. A lotion containing three grains of sulphate of quinine to an ounce of distilled water, and dissolved with a minimum of dilute sulphuric acid, was ordered to be used every hour as a wash for the conjunctival sac, and to be kept constantly applied as a compress to the lids.

Next day the oedema had much diminished, and by the 15th it had entirely disappeared. The conjunctiva on this day was more vascular and more swollen, but there was a suspicion of membrane on the inner part of the upper lid; there was not much discharge, and the cornea was still clear. The lotion was ordered to be continued, but to be used only every four hours. On the 19th, when the child was next seen, the conjunctiva had a healthier color, and was more granular; there was no membrane to be seen; the lotion was ordered to

be used three times a day. On the 26th there was again a small amount of membrane, this time on the lower lid, the conjunctiva covering the mucous surface of the upper lid was still granular, and no membrane could be seen there. The lids were again somewhat oedematous. The appearance of the conjunctiva, where the pseudo-membrane existed, was very like that which would be caused by painting the surface with white paint. When next seen—namely, on March 1st, both oedema and membrane had disappeared. During these three days the lotion had again been used every four hours.

From this time until March 15th the same lotion was continued, and applied three times a day. Notwithstanding the absence of any visible morbid exudation, the oedema and swelling of the lids disappeared; and on the 15th it was noted that there was slight cicatrization on the upper lid. The quinine lotion was then discontinued, and a mild lotion of boracic acid (two grains to the ounce) was substituted for it. This was used for a fortnight, when the patient was discharged as cured.

Remarks.—Mr. Tweedy observed that what he regarded as the success of the treatment of this case might not unreasonably foster the belief that the diagnosis was erroneous, and that the disease was not diphtheritic conjunctivitis at all, but rather an anomalous form of purulent ophthalmia. In anticipation of this objection, he called attention to the time at which the disease began, to its one-sided character, to the tense and brawny oedema of the lids, to the smoothness and pallor of the conjunctiva, to the reappearance of the peculiar phenomena when the applications of quinine lotion were prematurely reduced in frequency, and lastly to the sequential cicatrization. True, it would be easy to overlook the real nature of such a case if it were a unique instance. But this and similar cases could only be recognized and understood by reference to the behavior of typical examples of the disease. In the most pronounced form the characteristics of diphtheritic conjunctivitis are sufficiently conspicuous to arrest the attention of any moderately observant practitioner. The risk lay in overlooking the milder degrees, which at any time might be aroused into such activity as to lead to the rapid destruction of the cornea. The application of a solution of nitrate of silver, which is almost of essential service in the treatment of ordinary purulent ophthalmia in infants, is almost invariably disastrous when the conjunctivitis partakes of the genuine pseudo-membranous character. Mr. Tweedy referred to a case that had occurred in his own practice a few months before as an illustration of this. Arthur E. H., aged three weeks, was taken to the hospital for severe inflammation of both eyes on Oct. 9th, 1882. The right eye began to be inflamed when the child was a week old, and a few days later the left became affected. When first seen at the hospital (a fortnight after the beginning of the disease), the right palpebral conjunctiva was covered with thin, sticky, dirty-looking adherent pseudo-membrane; the cornea had sloughed and the iris was prolapsed. The left palpebral conjunctiva had a similar pseudo-membrane upon it, and was but very slightly vascular; the cornea was hazy throughout its whole extent, and had a well-marked abscess at the outer and lower part. Quinine lotion was ordered to be used every hour. Three days later the lids were apparently free from pseudo-membrane and presented the usual spongy, bright-red appearance of ordinary purulent ophthalmia. The cornea was rather cleared and the abscess more circumscribed. The discharge was likewise more purulent. Thinking that the special interest he had taken in the in-

vestigation of diphtheritic conjunctivitis might have induced him to exaggerate the gravity of this particular case, Mr. Tweedy adopted the actual indications of purulent ophthalmia and applied a ten-grain solution of nitrate of silver to the everted lids. Though the quinine lotion was continued every hour as heretofore, when the patient was taken to the hospital a few days later the left cornea had sloughed and perforated, and the iris was prolapsed. Had vascularity and swelling of the conjunctiva and the purulent discharge observed at the second visit been taken as an indication of the second or purulent stage of diphtheritic conjunctivitis, rather than as controverting the original diagnosis, the cornea, damaged as it was, might, Mr. Tweedy believed, have been eventually saved by persistent employment of the quinine lotion and by abstention from the nitrate of silver. In further support of the specific character of this pseudo-membranous conjunctivitis, he referred to a case seen in consultation with Dr. John Williams about eighteen months ago. An infant, about a week old, presented the signs of mild simple conjunctivitis, which was treated with weak alum lotion. In about ten days the inflammation had apparently passed off, and the child opened the eyes without difficulty. Suddenly the right lid swelled, and within twelve hours the cornea assumed the appearance of ground glass and became infiltrated at the lower part. Dense infiltrated pseudo-membranes soon appeared on the palpebral conjunctivæ of both eyes. Quinine-lotion was used every hour, day and night, and both corneæ were ultimately saved, though at one time during the treatment the child had suffocative attacks, and it seemed doubtful whether it could survive.

LEEDS GENERAL INFIRMARY.

ABDOMINAL TUMOUR; ASPIRATED THREE TIMES; FLUID CONSISTING APPARENTLY OF ALTERED BLOOD; SUBSEQUENT DISAPPEARANCE OF THE TUMOUR AFTER AN ATTACK OF DIARRHŒA AND COLIC.

(Under the care of Dr. CLIFFORD ALLBUTT.)

For the following report we are indebted to Mr. J. F. W. Silk, house-physician.

J. H. M., aged thirty, a tailor, was admitted on Sept. 7th, 1882, complaining of pain in the abdomen and constant sickness. He gave the following account of himself. About four years ago he first began to suffer from pain in the abdomen, coming on mostly after food, and associated with flatulence and acid eructations. This was put down to ordinary indigestion, and the attack passing off in the course of a couple of months he remained tolerably free from pain up to about five months before admission, when it recurred, and was accompanied by vomiting. At the same time he noticed a hard lump, the size of a closed fist, in the epigastric region, which, he says, disappeared a few days after the other symptoms had subsided. The whole duration of this second illness, including the disappearance of the tumour, was not more than ten days. Subsequently he had three precisely similar attacks, in a of which he noticed the tumour, and in all, except the last, this tumour disappeared in the intervals of comparative good health. The fifth and last attack commenced on June 18th, 1882, and although he was only confined to his bed a fortnight, he never recovered completely, as on former occasions, and the tumour, instead of disappearing as usual, increased in size. The pain and vomiting became more marked about a fortnight before admission, and he lost flesh. The first attack, four years ago, was ascribed to mental anxiety; the subsequent attacks

are all associated by the patient with excess either in eating or drinking—e.g., “a heavy supper,” “a copious draught of ginger-beer,” etc., but beyond that no definite exciting cause can be made out. Both the family and personal history are good. He denied all venereal affections, and, as far as one could make out, there were no signs of syphilis about his person; he has been very temperate, and on the whole has lived a remarkably regular life, free from any serious illness.

On admission he was found to be a highly intelligent man, with an anxious worn expression. The pain obliged him to sit up in bed, and he was constantly vomiting. He retained nothing but fluids, and of those preferred lemonade and other cool watery drinks; he was most free from pain when his stomach was distended with large quantities of such fluids. There were no signs of any excessive emaciation. The layer of adipose tissue was well developed, especially in the abdominal walls, but the whole muscular system was flabby and ill-nourished. On palpating the abdomen, a distinct rounded tumour could be felt occupying the whole of the epigastric region, extending downwards to the level of the umbilicus, and laterally beneath the ribs, inclining rather to the left of the median line. It was elastic and freely movable from side to side; but its connections, partly on account of the thickness of the abdominal walls, could not be made out with anything like certainty. It did not, however, seem to be attached to either the liver or spleen, which, as far as could be judged from the areas of dulness, did not appear to be enlarged. The deepest inspirations only caused a very slight downward displacement of the mass, and nothing like an hydatid “thrill” could at any time be detected. There was no ascites or cutaneous oedema, and no cardiac or pulmonary lesion. The urine was highly colored, and contained much mucus. The temperature was quite normal. He remained in hospital for nearly three weeks, and with careful dieting and complete rest, the urgent symptoms above-mentioned abated, the tumour became less apparent, the urine regained its natural appearance, and the mucus disappeared. He went out at his own request on September 23rd to attend once a week as an out-patient. He was readmitted on Nov. 15th, 1882. Although the vomiting had not returned, and the pain was much less, the tumour had increased in size and had extended a couple of inches below the umbilicus. Its connections were still a mystery, and even under ether nothing further was made out. While under the influence of the anæsthetic the long fine needle of a small syringe was plunged to a depth of about three inches into the tumour, and about a drachm of dark-brownish viscid fluid withdrawn. This fluid was highly albuminous, but gave no reactions with any of the usual tests for bile; microscopically it showed large numbers of broken-down blood-cells, granules of coloring matter, and some larger and more perfect nucleated cells of an epithelial type, but the most careful search failed to reveal anything in the shape of a hooklet.

On November 30th the tumour was aspirated at a point about three inches above the umbilicus, and thirty-two ounces of a fluid exactly similar to that described above were withdrawn; viewed *en masse*, it had a greenish tinge. Great relief followed the operation, and the tumour became less prominent and tense, although it by no means entirely disappeared.

On December 13th, as the tumour had nearly regained its former dimensions, it was again aspirated an inch below the seat of the former operation, and fifty-one ounces of the same dark-colored

fluid were withdrawn. After this second operation it was noticed that the right side of the tumour had diminished to a much greater extent than the left; so on the 18th another aspiration was performed, the point selected being about an inch and a half to the left of the second puncture. Thirty-two ounces of fluid were withdrawn, resembling in all respects that previously obtained. Immediately after the third aspiration the tumour collapsed, and could only be made out as an indefinite feeling of resistance on deep pressure in the epigastric region, as it did not subsequently increase in size, and the patient's general health was greatly improved. He was discharged on Dec. 26th, 1882.

After his discharge he was seen at irregular intervals as an out-patient, and up to the beginning of March of the present year remained free from pain and vomiting, the tumour gradually reappearing. About the 14th of that month he had a sudden and severe attack of abdominal pain and vomiting; this was followed by diarrhoea, the motions being quite black and loose. From that date, the patient said, the tumour has entirely disappeared, and when seen on May 11th there were certainly no signs of anything like a tumour to be made out in any part of the abdomen; and, except for an occasional feeling of “biliousness,” he says that he has been perfectly well ever since March.

Remarks.—The cyst in this case seems to have been composed of at least two cavities, probably communicating, but not freely. The sudden disappearance of the tumour, as if by communication with the bowel is remarkable; and although one can hardly expect that this disappearance will be permanent, still, from the fact that the tumour is now, after the lapse of two months, quite imperceptible, one is almost led to hope that such may be the case. In every other respect it resembles closely the first of the cases cited by Dr. Bristowe in his “Clinical Remarks on Abdominal Sanguineous Cysts,” reported in *THE LANCET* for August, 1885. The case cannot be said to be complete; and the subsequent history of the patient will, as far as possible, be carefully watched; but even in its present incomplete form it presents so many points of interest that it is not, perhaps, unworthy of record.

KING'S COLLEGE HOSPITAL.

PARALYSIS OF THE PALATE AND PHARYNX, COMPLICATED WITH PNEUMONIA, BOTH PROBABLY DIPHTHERITIC; RAPID RECOVERY; REMARKS.

(Under the care of Dr. FERRIER.)

For the following notes we are indebted to Mr. St. Clair Thomson, M.R.C.S., house-physician.

David C—, aged thirty-four, a strong, healthy-looking Covent-garden porter, came to the out-patient department on April 12th, 1883, complaining of difficulty in swallowing. He then had complete paralysis of the palate. It did not rise either in inspiration or phonation, and gave no reflex action. There was no affection of the tongue or lips. He could pronounce all the vowels, but could not pronounce the explosives; the voice was nasal in tone. He could whistle if the nostrils were closed, but not otherwise. Liquids, on swallowing, came back through the nose, but if that was held he swallowed fairly well. On being questioned, he stated that he had had a sore-throat fourteen days previously, and that soon afterwards he noticed some difficulty in swallowing, owing to the tendency of fluids to return through the nose. No further history of diphtheria could be obtained. Late on th

following evening, April 13th, he was admitted to the hospital, complaining of cough, feverishness, and inability to swallow. His temperature was 101.6°. The following morning he was found not to have slept at all, owing to the cough. He had swallowed nothing through the night. He was able to take milk into his mouth, but was quite unable to swallow it, even with the nostrils closed; the attempts to do so produced violent coughing and hawking. The voice was so nasal in tone that it was almost unintelligible; the condition of the palate remained as on the previous day. The temperature was 103°; the respiration 64, shallow, and chiefly thoracic; the cough was frequent, of a high-pitched, ringing character; the sputum, which was expelled with difficulty, was yellow and purulent. The front of the chest was resonant with scattered rhonchi and mucous râles; there was the same condition over the back of the right lung, and over the left base there was complete dullness below the fourth rib, with fine inspiratory râles and marked bronchial breathing. The pulse was 136, fair quality, and regular; the cardiac area and sounds normal. The urine was acid, sp. gr. 1028, turbid with urates, but free from albumen. He was fed by the stomach-pump twice a day, being given half a pint of beef-tea, half a pint of milk, one egg, and two ounces of brandy on each occasion. For his thirst, which was intense, he was allowed ice to suck. On the 15th the temperature was 102.6°, the pulse 134, and the respiration still 60. He had slept very little. On the 16th, the third day of admission, he coughed less, and slept well and quietly. He swallowed several ounces of milk with no choking and little coughing; the voice, though still nasal, was much clearer. The temperature fell to 101.2° and 100.6°; the respiration to 44 and 36, the pulse to 108 and 100 (taken morning and evening). On the 18th, the fifth day in hospital, he was able to swallow quite naturally, without choking or regurgitation through the nose. The palate moved both on inspiration, phonation, and on being touched. He could whistle and the voice was quite natural, having lost all nasal quality. The temperature had fallen to normal, the pulse to 80, and the respiration to 32. The dullness of the left base was less intense, the breathing was still tubular round the angle of the scapula, with some bronchophony. Feeding by the stomach-pump was from this date abandoned, and he fed himself by the mouth, but still with fluid diet. On the 31st, his eighth day in hospital, he was placed on full diet. The pneumonia and bronchitis cleared up and he was discharged, quite recovered, on April 30th.

Beyond the rest in bed and general treatment above indicated, he received no special treatment. As soon as he was able to swallow at all, he was given a sedative for his distressing cough, later on an expectorant, and afterwards a tonic of quinine.

Remarks by Dr. FERRIER.—Though in this case there was no clear history of diphtheria, yet we are justified in considering the sore-throat to have been of a diphtheritic nature by the course and termination of the paralytic symptoms exhibited by the patient. A local paralysis of the palate appearing within a fortnight after a sore-throat, rapidly involving most of the muscles innervated by the pharyngeal plexus, and terminating in complete recovery within ten days is typical of diphtheritic paralysis. The other symptoms exhibited by the patient—viz., the severe broncho-pneumonia—are also well known in connection with diphtheritic infection, and probably are of the same nature as the pathological changes in the lungs which result from paralysis of the vagi. In great measure the pneumonia is of a traumatic

nature from the entry of foreign bodies—food, drink, etc.—into the air-passages. Why the diphtheritic poison should specially affect the regions innervated more especially by the medulla oblongata has not yet been cleared up. There is no distinct relation between the severity of the throat affection and the subsequent occurrence of paralysis of the palate; and paralysis of the palate may occur as a local affection when the diphtheritic poison has entered the system at any part, as by the finger. The actual morbid changes characteristic of diphtheritic paralysis have been the subject of much recent investigation, the researches of Déjerine apparently establishing the existence of a parenchymatous neuritis secondary to a slight degree of myelitis of the anterior horns.

NEWCASTLE INFIRMARY.

STRICTURE OF OESOPHAGUS; GASTROSTOMY A DEUX TEMPS; DEATH ON THE EIGHTH DAY.

(Under care of Mr. PAGE.)

For the following notes we are indebted to Mr. Ernest Hudson, house-surgeon:—

C. S—, male, aged fifty-nine years, was admitted on April 9th, 1883. For fourteen years he had been a county court bailiff, and before that "boots" in an Edinburgh hotel. In early life he was a postilion. He stated that in May, 1882, he was eating hurriedly in a restaurant, when a portion of meat was arrested in its progress through the gullet at a point which he referred to the angle of Ludovious, and was immediately rejected. He had never before noticed any difficulty in swallowing. For six months the difficulty in swallowing solid food gradually increased; for five months before admission he had lived entirely upon liquid food. For the last ten days he had been unable to swallow even fluids. He had suffered pain of a gnawing character in the epigastrium. He was treated at first by a druggist, and subsequently by a medical man, for indigestion. Four months before admission a bougie was passed, and he was told that he had a small cancer of the gullet. No assignable cause of the stricture could be made out. There was no history of syphilis, and he had never swallowed any irritating substance. There had never been hæmatemesis. During his career as hotel "boots" he drank very freely, sometimes as much as half a bottle of whiskey a day. There was no family history of tumour of any kind. He had lost 3st. in weight since his illness began. Pulse 120, small, irregularly intermittent; respiration shallow, chiefly thoracic; tongue dry and brownish; abdomen much shrunken and fallen in. Mr. Page passed a full-sized oesophagus bougie, which was arrested eleven inches and a half from the teeth. He was given a teaspoonful of milk, which, though apparently swallowed, was returned after about half a minute into the mouth. Ordered enema containing one ounce of brandy and three ounces of beef-tea thrice daily. It was eventually decided to perform gastrostomy.

April 15th: Chloroform having been administered, Mr. Page made a superficial incision, commencing at a point on the left of, and an inch and a quarter from the lip of the ensiform appendix, extending downwards for two inches and a quarter, parallel with, and an inch and a quarter from the lower thoracic margin. The fascia transversalis was exposed by a series of careful incisions. Two small vessels were ligatured and two more torsioned. All oozing having ceased, the fascia, and subsequently the peritoneum, were divided upon a hernia director. Through the opening thus made Mr. Page withdrew, with the finger and

thumb of the left hand, first a portion of the colon, which he returned, then a portion of the omentum which led up to the great curvature of the stomach, the anterior surface of which was attached to the edges of the incision through the fascia transversalis and the parietal layer of the peritoneum by interrupted sutures of silkworm gut, four on either side and one at the inner extremity. The surfaces of the outer extremity of the wound were brought into, and retained in, apposition by two superficial interrupted catgut sutures. A small portion of sponge was placed between the surfaces of the wound. Protective and carbolic gauze, Listerian dressing. The carbolic spray was used throughout the operation, which lasted fifty-nine minutes.—15th: No vomiting; no pain. Has been fed every four hours with enemata of beef-tea and brandy. At 11.30 p.m., restless; three minims of solution of morphia injected hypodermically; slept quietly until 3 a.m. Micturated voluntarily. Evening temperature 100°. 16th: No pain. Fed by enemata, last two of which have not been retained. At 9 p.m. (sixty hours after operation) Mr. Page made with a bistoury a small opening into the stomach, a No. 8 indiarubber catheter was introduced, though which fluid food was injected, and by which he was fed until his death. Temperature 100°; pulse 130; respiration 36.—17th: Complaints of slight uneasiness over right lateral thoracic region. Temperature 100°; pulse 120; respiration 26.—18th: No pain. Morning temperature 99°; evening temperature 101.2°; pulse 120; respiration 26.—19th and 20th: The temperature has varied between 100° and 102°; pulse 120; respiration 28.—On the 19th he commenced to ramble, and continued to do so until his death.—On the 22nd he died, 160 hours after operation.

The necropsy was made thirty-four hours after death. The surface exposed in the wound was greenish in color, and emitted a slight putrefactive odor. No effort of repair had been made in the wound in the abdominal wall, or of union between the apposed surfaces of the parietal and visceral portions of the peritoneum in this region. On opening the abdomen no serous or plastic peritonitis was found. The stitches uniting the stomach to the abdominal parietes were quite firm, and the tissues in the neighborhood presented no appearance of ulceration or inflammation. The opening into the stomach was situate an inch and a quarter from the great curvature, and four inches from the pylorus. The stomach contained a small quantity of clotted milk; the mucous membrane was pale and somewhat opaque, and coated with a tenacious mucus. In the oesophagus was situated an ulcer, two inches long, its upper part being five inches from the upper border of the cricoid cartilage, occupying almost the entire circumference; its edges were irregular, overhanging, but not indurated; its base flocculent and pale, and soft to the touch. Heart weighed eight ounces, was encased in much fat, its substance pale and easily broken down under the thumb, and valves healthy. No pleuritic adhesions existed. Both lungs were very oedematous. The upper lobe of the right lung was consolidated, crepitation was absent, and it broke down readily on pressure. The right lung weighed thirty-six ounces, and the left lung twenty-three ounces and a half. The right kidney weighed five ounces and a half. The capsule was slightly adherent. Projecting from the surface were two cysts, one about the size of a marble, the other slightly smaller; both contained a yellowish serous fluid; the substance was pale and somewhat tough. The left lung weighed five ounces, and contained one similar but smaller cyst.

GUY'S HOSPITAL.

CASES OF DISEASE OF THE UPPER JAW.

(Under care of Mr. BRYANT.)

CASE 1. *Periosteal (?) Sarcoma of Anterior Surface of Upper Jaw; Removal; Recovery.* (Reported by Mr. Franklyn Brown.)—Edith C—, aged nine years, was admitted into Lydia ward on June 30th, 1881. The patient's father, aged thirty, was healthy, but her mother, aged thirty-two, had suffered from rheumatism. Six months before admission the patient received a blow on the right cheek, and soon afterwards noticed a small swelling, which for a time remained stationary, but for the last three weeks it had increased. About two months before admission it was punctured, but with no result.

On admission, there was a slight swelling on the right cheek over the malar bone, deeply placed and movable over the bone "with an elastic feel." The superficial structures were freely movable over the tumour. The finger could be placed between the tumour and the teeth. Size about .75 in. by .5 in. Nostril free, lacrymal duct free. On the right side she had permanent incisors and the six-year old molar, also the temporary canine and temporary second molar. The first molar had been shed. On July 1st the tumour was removed from inside by scissors. It was easily separated from the bone. Iodine water was applied and a sponge inserted. The tumour was solid and a good deal of muscle was removed. On section it had a uniform translucent aspect and a firm close texture. It measured about 1.5 in. long by .75 in. broad. On July 12th the patient left the hospital well.

CASE 2. *Anal Abscess of twenty years' standing; Sinus on Palate; Incision and Extraction of the Root of the Right Lateral Incisor; Recovery.* (Reported by Mr. Tresidder.)—Charlotte M—, aged thirty-two, a glovemaking, was admitted on May 13th, 1881, into Lydia ward. Her parents are living. Mother, brothers, and sisters healthy. Her father suffered from urinary trouble. Twenty years ago the patient had a blow on the upper lip; the teeth became very tender, and two or three years later she noticed a swelling on the superior maxillary bone. This swelling increased for about five years, and had since remained pretty stationary. This swelling was lanced, and she derived much relief. It was afterwards lanced from time to time, but no cure had been effected.

On admission, the patient looked a healthy young woman. Her right upper jaw was much swollen, pushing forward the skin and dilating the right nostril. There had been no discharge from the nostril. The swelling hedged into the mouth, forming an enlargement about the size of a large walnut situated in the anterior part of the roof. All the teeth had erupted. The eyeball on the affected side was not displaced. The mucous membrane of the right nostril was abundantly red, and there was a foul odor like ozæna. The nostril was quite free. Pressure on the teeth and alveolar process caused no pain, and gave no sensation to the fingers of crackling. The patient stated that when she was about fourteen or fifteen, and when her face was a little swollen owing to toothache, she had her right upper bicuspid tooth extracted. She had also lost her left upper bicuspid tooth, and all her four second molars had decayed and broken away, the stumps only remaining. The stumps of the bicuspid teeth were also in the patient's head.

On May 24th the palate opening was enlarged, when the finger easily entered into a large cavity, evidently the antrum. The upper part was full of

soft material, and some foul-smelling dark fluid escaped. On hooking the finger forwards towards the alveolus a sharp fang of a tooth was discovered projecting into the cavity. This proved to be the fang of the right second lateral incisor. This tooth was now extracted. The cavity was cleared out, and a sponge inserted. The tooth was dark above the crown, and opaque and light. The extremity of the fang was bare and discolored. The rest of the fang was covered with a number of small, irregular, brownish excrescences resembling tartar. There was no membrane covering the tooth at all, and the fang had evidently been bathed in pus for some time.

On June 5th the patient had learnt to wash out the cavity with solution of permanganate of potash. The discharge was almost nil. The naso-lateral fold reappeared. The patient being almost well was discharged.

GENERAL HOSPITAL, BIRMINGHAM.

TWO CASES OF TUBERCULOSIS OF THE MALE GENITOURINARY ORGANS; REMARKS.

For the following notes we are indebted to Mr. J. W. Bond, resident medical officer, and Mr. B. C. A. Windle, pathologist.

CASE 1. (Under the care of Dr. Wade.)—G. C—, aged forty-three, a cooper, was admitted on Oct. 12th, 1882, when the following notes were taken. There was no history of tuberculosis in his family. For the past twelve months he has had a cough and a little hæmoptysis. Nine months ago he complained of increasing weakness, pain in the right chest, and a cough accompanied with greenish sputum. Four months ago the patient noticed scalding during micturition, the urine passed being normal in appearance. For the last three months, after a good deal of straining, he passed urine containing pus and sometimes blood. He has had for the same time a constant aching pain in the left groin, with incessant desire to micturate. Micturition did not afford any relief to this, but was accompanied by pain shooting down the urethra.

On admission he stated he had chills daily, after which he turned very hot, and he had pain under his left ribs. During and after micturition he has pain which shoots from the left groin along the penis. Has a bad cough, spits up a little blood, and feels very ill. The patient was strong enough to walk into the ward; his expression was anxious, and face flushed; he was very thin, and skin dry: temperature 102°. There are traces of old suppuration over the lower end of the sternum. He had micturated forty times in the last twenty-four hours, the stream being about the size of No. 3 catheter (English). It is not forked or twisted. Pressure over the left renal region causes pain which shoots to the end of the penis. There is no stricture. The urine is acid, with a sp. gr. of 1020, and contains much albumen and pus. Respiration 26; *alæ nasi* working; an occasional short cough; voice husky. He coughs up about two ounces of sputum per diem, streaked with blood and muco-purulent; ulceration about vocal cords; extensive consolidation of both lungs; no diarrhoea; no vomiting. From this time the patient rapidly got worse, becoming more emaciated, suffering from profuse night sweats, daily losing strength, and, in fine, presenting all the characteristic symptoms of a case of acute phthisis. During the whole period of his stay he had a constant desire to micturate, only passing a small amount each time. He suffered from pain above the pubes, and, for a few days, from retention, which had to be relieved by catheterization. On the first occasion on which

this was attempted a small instrument was used. This could not be passed into the bladder, but appeared to be caught in a stricture. A large instrument was, however, readily introduced.

The patient died on November 2nd. The necropsy was made next day, when the following condition of the urinary organs was found:—Kidneys: Right was normal, as was its ureter; left, there was a circle of caseous substance around the pelvis, and there were a few tubercular nodules in the ureter. Bladder: The walls of this organ were extremely ulcerated, and in parts very thin, notably so at the superior aspect; masses of breaking-down tubercular deposit hung from the walls; the prostate was slightly enlarged and tubercular; at the vesical end of the urethra there were three masses of deposit, extremely firm in substance, which met to form a tricuspid valve, which closed the orifice; one of these was placed below, the others on each side; in the urethral aspect of the lowest was a small pouch about a quarter of an inch deep. The bladder contained a small amount of dark-brown intensely fetid urine, with flakes of deposit from the walls floating in it. Both vesiculæ seminales were enlarged and contained caseous matter. The larynx, lungs, and intestines showed advanced tubercular disease; the other organs were normal.

CASE 2. (Under the care of Dr. Rickards.)—A. B—, aged thirty, fireman, was admitted on March 12th, 1883. His father died of phthisis. He himself had suffered from a previous attack of congestion of the lungs. About twelve months ago, the patient for about half an hour was unable to micturate, though strongly desirous of so doing. After this time he experienced pain at the end of the penis preceding micturition, whilst during that act he had a scalding sensation. The urine itself, he noticed, became thick, and especially after much exercise or standing deposited "matter." Occasionally it contained blood. This state of affairs continued up to admission. He has made water very frequently, sometimes every five minutes. The quantity per diem has been considerable, and its smell offensive. Occasionally he has had an aching pain in the belly, especially to the right of the navel. He has had no pain in the back, no shooting pains from loins to penis, or down the thigh. Three weeks ago he had a rigor, and since he has had slight cough, and has lost much flesh. Has passed no calculi per urethram.

On admission, the patient was a thin man with flushed cheeks, bright eyes, *alæ nasi* working, and an anxious expression. He lay on his back, breathing quietly, respiration 26 per minute. Temperature 101°F. His voice was feeble and husky; there was extensive consolidation of the right lung; the other thoracic organs were normal. There was pain on pressure in the region of the right kidney. The patient micturated about every fifteen minutes, the urine being of a neutral reaction, sp. gr. 1015, and containing much pus. Nothing was found on examining the rectum and testes, except extreme tenderness on pressing the prostate. The man's great complaint was his constant desire to micturate. After admission, the patient rapidly became worse, the lungs breaking down, the temperature high at night, and the frequent micturition continued. The urine varied in quantity from forty-six to eighty ounces, in sp. gr. from 1014 to 1020, and always contained much pus. Tubercle bacilli were present in the sputum. On March 23rd, the patient was examined by Mr. Barling, who favored us with the following report:—"No stricture. On sounding surface of bladder behind prostate feels hard and rough, but no distinct calculus can be detected. Per rectum: Prostate and part of bladder adjacent appear to be considerably thickened." On March 28th, the pa-

tient, after sitting up, suddenly fell back and died. For five days previous to his death the amount of urine had steadily decreased.

Autopsy.—Heart contained a large amount of firm yellow clot, otherwise normal. Lungs: Right, cavity at apex; lower part of upper lobe and middle lobe full of tubercles and small cavities; lower lobe contained a number of miliary tubercles. Left, miliary tubercles scattered throughout organs, a few small cavities in apex. Kidneys: Right, pelvis contained pus, and was surrounded with tubercular deposit, which extended into the ureter. Several pyramids were broken down and formed cavities full of pus. Ureter contained some tubercles. Left: A number of small caseous deposits occupied pyramids at centre of kidney. Pelvis contained a considerable amount of lithates. There were a few tubercles and tubercular ulcers in ureter. Bladder: Full of pus, and on removal apparently consisted of two equal sized cavities, communicating by a small hole. A more extended examination showed that the anterior cavity was the prostate completely hollowed out and forming a cyst of the same size as the posterior cavity, which was the somewhat diminutive bladder. The walls of both these cavities, but especially the prostatic, were much ulcerated and covered with large masses of deposit. Both vesiculæ seminales were enlarged and full of caseous matter. Testes: Right, contained a cavity full of pus, and some caseous masses; left, contained some very soft caseous masses. There were a few tubercular ulcers in the colon near the ileo-cæcal valve. The other organs were normal.

Remarks by Drs. BOND and WINDLE.—The chief clinical interest of the first case lies in the anomalous symptoms produced by the deposits at the neck of the bladder. Examination post mortem showed that when a small silver catheter was introduced it was almost certain to catch in the pouch already described as existing in the lowest segment of the valvular apparatus. The cavity being too small to admit the point of a larger instrument, explains the ease with which a No. 9 catheter surmounted the obstacle which a No. 3 had failed to pass. In the second case, it seems strange that a catheter should have passed across so large a cavity as was formed by the excavated prostate, and entered with such ease into the bladder. That this was the case, there is no doubt, as Mr. Barling felt the instrument, per rectum, in the bladder behind the prostate. Pathologically, these cases are interesting from the very unusual amount of tubercular destruction present—in the first in the bladder, and in the second in the prostate. The former case is an exception to the rule that tubercular disease of the urinary tract commences in the kidneys and subsequently appears in the ureters and bladder. Here the bladder was extremely affected, whilst in only one ureter and kidney were there signs of disease, and in those but small evidence. The latter case would appear to be of the same nature, though in it the kidney mischief was more advanced than in the former. At the same time it was considerably behind the condition of the other parts of the tract, notably the prostate.

EAST SUFFOLK AND IPSWICH HOSPITAL.

THE ENTIRE SCALP COMPLETELY TORN OFF.

(Under the care of Mr. HETHERINGTON.)

M. W—, a girl, aged fourteen, a stay maker, on February 19th, while working in the factory where she was employed at her sewing machine, which, in common with others, was driven by an unprotected shaft passing under the table, she

stooped down to find something she had dropped, when her hair, which, contrary to the rules of the establishment, was loose and very long, fell over the shaft as it was revolving, and so was wound round and round on it until the scalp was completely torn from her head and the poor girl then set free. She was immediately sent to the hospital, when it was found that in front the entire scalp and forehead, just below the right eyebrow, across the root of the nose, through the left brow, behind to the nape of the neck, on the right side, including half the ear, and on the left just escaping the ear, was completely gone. The greater part was torn off, leaving the edges as if cut with a knife; on the right side the skin, however, was more or less lacerated where the ear was severed, and behind the skin hung down away from the neck. The patient was perfectly conscious and able to describe the accident, and apparently not suffering from shock; while considering the best means of dressing such a large surface, the scalp which had been detached from the machinery was brought, and it was decided to replace it, although small hope of its union was entertained. The hair having been cut off and the scalp washed in warm carbolic solution, it was replaced, the retracted skin of the face and neck being drawn up and secured to it by silver wire sutures, the whole being completely covered with cotton-wool and moderate pressure applied. The temperature rose the next day to 103° 8', and the pulse to 140, but from this time gradually fell to normal; there was no sickness. For the first six days milk only was given.

February 23rd: Part of the scalp behind was removed to enable the neck to be dressed, the discharge here being very profuse. There was also considerable hæmorrhage from one spot.—25th: The dead scalp was removed, the surface beneath was found healthy and granulating, with bare bone in one or two spots; a few small sloughs removed. The dressing which was then used, and has ever since been continued, was vaseline spread on strips of lint, the whole covered with cotton-wool.

May 31st: The large granulating surface is slowly diminishing in size; skin-grafting is being successfully adopted, although it must necessarily take a long time before it is completely healed. No cerebral symptoms have at any time been present.

Remarks.—That the entire scalp can be detached with so little shock or other injury is remarkable. Dr. Samuel Gross, in his "System of Surgery," narrates a very similar case of a young woman whose scalp was in the same way torn off by machinery. Eighteen months elapsed before the surface completely cicatrized; the woman, moreover, was at the time of the accident three months advanced in pregnancy and carried the child to full term. Such accidents point to the necessity of carefully guarding and protecting exposed driving shafts and gear in factories, etc., especially where females are employed.

LEEDS FEVER HOSPITAL.

A CASE OF SCARLET FEVER WITH COMPLETE RELAPSE.

(Under the care of Dr. BARRS.)

FOR the notes of the following case we are indebted to Dr. Crooke, resident medical officer.

Ada S—, aged twenty, a domestic servant, was admitted into the hospital on February 17th, 1883, when she presented the following evidences of an all but terminated attack of scarlet fever. The face was flushed; there was slight febrile disturbance, and the tongue was furred and moist, with some redness of the tip. The throat was considerably injected with much swelling of the tonsils,

but no ulceration of the surface. There were the remains of a rash upon the chest. The urine was not albuminous. She said that the attack had commenced on the 14th (three days before admission), with sore-throat and feverishness, headache, a rigor and vomiting, and that a well-marked rash was visible on the morning of the 15th. She was sent to the hospital by her medical attendant as a case of scarlet fever. The temperature curve, though on and after admission more or less unsteady, never showed any marked rise, and may be said to have been of normal mean almost from the first.

On March 7th, the patient was allowed to leave her bed, though still confined to her small ward. Previous to this date the temperature was noted as normal or subnormal on five or six days. On the 16th, between which date and the 7th we may assume the temperature to have been normal, though no actual observations were made, she shivered, and was noticed by Dr. Crooke to be looking unwell; and, in addition to the general appearance of a febrile attack, she complained of sore-throat. The tonsils were found to be swollen. On the evening of the 17th, a well-marked scarlatinal rash was seen on the neck, trunk, and extremities. The temperature was 104°. On the 18th, the rash was still more marked, the temperature 100° to 102°, and the tongue presented a typical appearance with enlarged papillae. On the 23rd, desquamation appeared about the neck. The temperature was normal on the 20th. On the 27th, desquamation was general. She desquamated freely after the first attack from Feb. 24th to March 7th. The urine was free from albumen throughout both attacks, and also on April 27th, when she left the hospital.

Remarks by Dr. BARRS.—Cases of true relapse in scarlet fever—that is, where all the characteristic phenomena of the disease are developed within a very short time of a previously complete manifestation of infection—are rare. That the case was one of scarlet fever, with true relapse, there can be little doubt, though we had not an opportunity of seeing the primary attack in its complete development. The only and the great source of error in such a case is the almost unlimited uncertainty of the diagnosis in this disease. The occurrence of a red rash of, at the best, very ill defined character, with sore-throat and pyrexia, will by no means warrant us in making a dogmatic statement, always, that any case is one of scarlet fever. That the second attack was one of scarlet fever there could be little doubt, and that the first was of the same nature is almost certain by the fact, which was afterwards learnt, of there having been cases of scarlet fever in the house in which she had lived. Beyond the bare facts of the case, showing, that one or the other can occur, there is nothing to lead us to determine whether relapse was due to the "recrudescence" of the primary infection, or to the failure of the first attack to protect. The possibilities of either, whatever the first may mean, can scarcely be discussed here.

SHEFFIELD PUBLIC HOSPITAL AND DISPENSARY.

MIXED-CELLED SARCOMA OF THE LOWER END OF THE FEMUR; AMPUTATION THROUGH THE MIDDLE OF THE THIGH; RECURRENCE IN THE LUNGS; DEATH; NECROPSY; REMARKS.

(Under the care of Mr. PYE-SMITH.)

For the following notes we are indebted to Dr. Sinclair White, house-surgeon.

Alfred H—, aged nineteen, a delicate-looking

youth with a family history of phthisis, was admitted, on Jan. 8th, 1883, suffering from a tumour in the lower part of the right thigh. He stated that he had had "growing pains" about the right knee for three or four months, and that these were followed six weeks ago by enlargement, which had increased rapidly; he had, however, kept at work as a moulder until admission. Afterwards, he remembered that two years previously he had had a blow from a cricket-ball, which caused a severe bruise of the knee.

Examination revealed an oval swelling situate over the internal condyle and a portion of the shaft of the femur immediately above. Manipulation showed the growth to be connected with the subjacent bone. The skin over it was normal. The swelling felt firm, smooth, and slightly elastic. The inguinal glands were not enlarged. An exploratory incision having been made into the growth and its malignant character ascertained, amputation through the middle of the thigh was performed on Jan. 10th. The wound was treated antiseptically, and healed without suppuration. The boy was discharged apparently well on Feb. 21st.

Microscopical examination of the growth showed it to be a mixed-celled sarcoma, with a few bony spicules. It originated from the periosteum, and involved the internal condyle and an inch or so of the inner side of the shaft of the femur.

The boy continued well up till April 10th, when he began to suffer from cough and shortness of breath which he attributed to catching cold. He was readmitted on April 21st when both lungs were found to have irregular patches of dulness; crepitation and pleuritic friction sounds could be heard over the greater part of both lungs. Temperature rose to 103° F., and the boy suffered greatly from dyspnoea and inability to lie down. He got rapidly worse, and died on April 28th.

Necropsy.—The right lung was infiltrated with new growths, and a number grew from its pleural covering. The growths were of various sizes, from that of a pea to that of a hen's egg. They were also variable in color and consistence. Some were as firm as liver, and of a whitish color, not unlike hardened brain. Others, with the same color and consistence, cut with a "sandy" feel, as if they were infiltrated with fine sand. Other growths, again, were of a darker color and softer consistence, while some were even diffuent and fluctuating. The growths were but slightly attached to the lung or pleura, and could be readily isolated. The right pleural cavity contained a large amount of reddish-colored serous fluid. The left lung had similar growths, only not so numerous. Growths were also found behind the sternum and in front of the dorsal vertebrae in the mediastinal spaces. The heart presented suspicious-looking patches in the inter-ventricular groove. The kidneys appeared normal, except for a little puriform deposit in the neighborhood of the pelves. The liver, spleen, and intestines were healthy. The brain was not examined. Sections from the growth showed them to be composed of round and ovate cells, closely packed together, the new growths infiltrating the lung tissue and distending the alveoli, the outlines of which were still visible. The stump of the femur was free from a recurrence of the growth.

Remarks by Mr. PYE-SMITH.—This case proved to be, unfortunately, typical and complete. Malignant sarcoma being diagnosed amputation in the thigh, well above the growth, was chosen rather than amputation at the hip, because on the one hand the risk of the operation would be less, and the stump (in case of success) would be more useful; whilst, on the other hand the danger of re-

currence seemed to concern remote parts quite as much as the neighborhood (infection in sarcomata of bone being by the blood rather than by the lymph stream or by continuity of tissue), and as it seemed just possible before operation that the case might turn out to be one of myeloid, it would have been a pity to remove, in that case unnecessarily, the whole of the femur. The important question is, Did the removal of the original tumour either retard or accelerate the development of secondary growths? or had it no effect in either direction? The operation had a decided effect in removing anxiety and bringing hopefulness to the patient, and the fatal internal ailment was probably less distressing to him, both physically and mentally, than if it had been complicated by the presence of a visible tumour.

ST. VINCENT'S HOSPITAL, DUBLIN.

A FATAL CASE OF UNCOMPLICATED ACUTE RHEUMATISM; REMARKS.

(Under the care of Dr. QUINLAN.)

For the following notes we are indebted to Mr. Kenna, house-surgeon:—

Kate C—, aged twenty-two, single, of delicate appearance, was admitted on Friday, May 11th, suffering from acute articular rheumatism. She had been ailing for seven days; no previous attack. Both wrists, both elbows, and the left knee were swollen and immovable, and very painful; tongue yellowish white; copious acid perspiration; no cardiac lesion; no subcutaneous nodules. Temperature 103.8° F.; pulse 120. Ordered fifty-grain doses of salicin in milk, commencing at noon; also a quarter of a grain of morphia, hypodermically. At 6.30 P.M. she had taken six doses; the pain of joints was not so severe; temperature 100.8°; pulse 112. Ordered the salicin every second hour if not asleep.

May 12th, 9.30 A.M.: Articular pain completely gone; slept a few hours during the day; temperature 100.5°; pulse 120. Ordered sixty grains of salicin every second hour until evening. 6.30 P.M.: A little articular pain; temperature 101°; pulse 120; the patient restless. Ordered a sleeping draught containing chloral and bromide of potassium. To continue the salicin every second hour.—13th, 9.30 A.M.: Slept well during the night; articular pain gone; heart normal; temperature 100.6°; pulse 128. To continue salicin.—14th, 9.30 A.M.: Slept without a draught; free from pain; heart normal; she is, however, feverish and uncomfortable; intellect quite clear; temperature 100°; pulse 116. To continue salicin. 6.30 P.M.: Temperature 102.8°; pulse 112. At 11.30 P.M. the patient suddenly became delirious and violent. The temperature rose very much; but as she had to be kept in her bed by the efforts of three persons, it could not be exactly ascertained. She died about a minute before midnight.

Remarks by Dr. QUINLAN.—Having recently put forth some very successful cases of acute rheumatism treated by large and frequent doses of salicin, I feel it incumbent to publish this, the first of a large number of them in which the result was unfavorable. The very high admission temperature, and the frequent temperature exacerbations, marked this case from the beginning as one of those virulent ones that used to be the dread of physicians and an opprobrium to medicine. I am almost inclined to regret that, with this knowledge before me, I did not begin with sixty-grain hourly doses, and adhere to them until the temperature was decisively lowered and the disease evidently subdued. Probably, however, in so virulent a

case the result might have been the same. It is remarkable that, although the temperature heightened again and again, the influence of the drug in relieving the articular pain was immediate and complete. Something also might have been done by blistering the epigastrium, a procedure which often does good in severe cases, and that quite irrespective of cardiac complication. The fatal issue does not in the least shake my confidence in salicin. It shows, however, that we have something yet to learn about the exact method of using it, and that we do not yet always administer it with sufficient boldness.

ST. BARTHOLOMEW'S HOSPITAL, CHATHAM.

ACUTE TRAUMATIC TETANUS, COMPLICATED WITH FACIAL PARALYSIS; DEATH; REMARKS.

(Under the care of Mr. NANKIVELL.)

J. G. L—, aged thirty-three, a working man, attended the out-patient department on March 12th, 1883, suffering from a slight attack of facial erysipelas, caused by a wound of the bridge of the nose, received two days previously whilst at work. He was treated as an out-patient till March 17th, when, feeling quite well, he at his own request was discharged.

On March 19th, he again presented himself, stating that on the afternoon of the 17th he noticed he could not open his mouth or close his right eye. He was made an in-patient.

State on admission.—The lines and markings on the right side of the face are obliterated, and the eye is wide open and cannot be closed. The mouth and tip of the nose are drawn over to the left side, and his lower jaw can only be opened so as to admit of the introduction of the handle of a spoon. The man has no ear symptoms. Ordered some calomel and jalap and a mixture containing ten grains of iodide of potassium three times a day.—20th: The paralysis of the face can be completely neutralized by a mild galvanic current applied over the seventh nerve. Patient's breathing is considerably affected, being whistling in character. Trismus much the same.—21st: Complaints of pain at epigastrium. The muscles of the neck and back feel hardened. Ordered belladonna and chloral.—23rd: Early this morning the patient had a very severe spasm of the muscles of respiration, being nearly asphyxiated. There was also opisthotonos. The paralysis of the face still exists, and the trismus is as complete as ever.—24th: Has had several general spasms since yesterday. He died this afternoon.

Remarks by Mr. NANKIVELL.—Acute tetanus, conjoined with paralysis of the seventh nerve, must be a rare affection. I have seen a tolerably large number of cases of tetanus, but have never met with this complication. The muscles of the face are usually in a state of tetanic contraction, producing the "tetanic grin," which was entirely absent in the case now under consideration. Mr. Poland, in his article on Tetanus in Holmes's System, states that in two cases of tetanus at Guy's the orbicularis palpebrarum was involved, inducing closure of the lids. In my patient the eye was wide open and could not be closed. The text-books I have been able to consult do not mention tetanus complicated with facial paralysis. I have, therefore, thought it desirable to place this case on record. I would add, in conclusion, that March 17th, the day on which the man last came to the hospital as an out-patient, was cold and wet. It has occurred to me that he might have caught cold on his way home, and so induced inflammation of the nerve within the aqueductus Fallopii, which would account for the paralysis.

WEST LONDON HOSPITAL.

PARAPLEGIA IN A CHILD CURED BY PURGATIVES;
REMARKS.

(Under the care of Dr. THOROWGOOD.)

For the following notes we are indebted to Dr. Schacht, house physician:—

Jessie P—, aged ten years, was sent into the hospital as a case of infantile paralysis on Feb. 2nd, 1883, when the following notes were taken:—The mother says that for over three months her child has not been able to walk; she has seemed to fail gradually, and now is quite unable to stand. When placed on her feet she falls unless caught by a bystander. The legs are not notably wasted, but the mother says she has lost flesh decidedly of late. The patellar reflex movement well displayed and critically tested. The general surface of the back is rather tender, but no special pain over the spinal column, and no pain or other symptom when the head is pressed down on the spine. No "tache cérébrale." Urine is healthy and free from albumen and sugar; pupils of eyes dilated notably. Pulse quiet; tongue not clean. In reply to inquiry the mother reported that her daughter was sorely troubled with worms—ascarides. In the belief, therefore, that irritation of the intestines might have something to do with the paraplegia, the following medicine as a non-irritating antacid aperient was prescribed on Feb. 2nd, containing half an ounce of compound decoction of aloes, to be taken twice a day. On the 6th the child was able to run and walk about the ward as well as could be desired. The medicine had acted efficiently on the bowels, and brought away many worms. She continued it a few days longer, and on Feb. 10th, as she seemed perfectly well, she was given a tonic with iron and allowed to go home, with orders to return if any symptoms of illness showed themselves.

Remarks by Dr. THOROWGOOD.—Cases of paraplegia, and sometimes of contraction of the knee, of apparently obstinate kind, have been met with, where the cure has been missed from a want of attention to the condition of the intestinal canal. The late Dr. Graves, of Dublin, gives a case where a youth who had fed freely on nuts had a distinct attack of paraplegia only cured by the effectual purgation of his intestine from the crude mass formed by undigested nuts. The presence of intestinal worms in the case of Jessie P— clearly indicated the line of treatment to be first put in force.

Medical Societies.

EPIDEMIOLOGICAL SOCIETY.

Outbreak of Cholera in Egypt.

At a meeting of the above Society on July 4th, Dr. J. M. Cunningham, Sanitary Commissioner with the Government of India, read a paper on the "Sanitary Lessons of Indian Epidemics." The President of the Society, Dr. George Buchanan, F.R.S., introduced the subject by the following memoranda concerning cholera:—

1. *Narrative.*—Cholera reached Europe by way of Egypt for the first time in 1865. Before that date, its course from Asia had been through the Russian Empire. At the first appearance of cholera in Europe, over forty years ago, it began in Great Britain fifteen months after its introduction to Europe. At its second appearance, it began with

us in England after about the same interval. Its third appearance does not admit of comparison with the others. At the fourth appearance of cholera in Europe; when it came by way of Egypt, it was epidemic in the Hedjaz in May; it appeared at Alexandria on June 2nd; was at Malta, Smyrna, and Constantinople before the end of that month; and appeared in Spain and Italy and at Marseilles during July. Spreading somewhat widely in Europe during the next two months, it was at Southampton on September 17th, and on Nov. 3rd it was witnessed at New York. In the spring of 1866, cholera acquired an increased diffusiveness; and by June had attacked many places in the United Kingdom, but hardly any cases occurred in London until July. [The Suez Canal was opened in November, 1869.] Extension of cholera from Northern Arabia was next threatened in 1871; and the disease prevailed to a small extent in Europe during 1872 and 1873. Since that date, it has occurred several times among the pilgrims to the Holy places, but has not established itself in Egypt, nor has it prevailed in Europe. Cholera is now at Damietta, a place with some 30,000 inhabitants, about six miles from the mouth of one of the branches of the Nile. The way of its arrival thither cannot be stated. Damietta is not on any high road from Asia; and the towns above Damietta on the Nile are not known to have been affected before this town. No cholera is known of at Suez, nor in the course of the Canal, though from Port Said an occasional death is now being reported. In the ten days ending June 30th, about 500 deaths from cholera occurred at Damietta; on July 1st there were 140; on the 2nd, 130; and on the 3rd, there were 110 deaths. The disease now exists at Mansourah, higher up the same branch of the Nile, and cases are appearing in other towns situated on the railways of the Delta.

2. *Expectations.*—When, I have been asked, may cholera be expected to travel through Europe to England? how long after its present manifestations in Egypt? Evidently no medical data exist for an answer to the question. We do not understand all the conditions for the diffusion of the disease. But we in England do firmly believe, what many of our Indian friends would deny, that cholera is influenced in its spread by human intercourse. We do not affirm that it passes from person to person as small-pox or typhus does; but we believe that it extends much after the fashion with which we are familiar in the case of enteric fever, by means of the discharges from the sick, particularly if those discharges are received into foul cess-pools and drains, or if they obtain admission into drinking water; and human intercourse is one of the conditions for the spread of cholera in such fashion as this. If we now, for the sake of hypothesis, suppose other conditions for diffusion of cholera to be to-day what they were in 1865, we may inquire how far the conditions of human intercourse have altered in such wise as to affect the probable dissemination and rate of transmission of cholera in and about Europe. In reply, let it be remembered that, though Egypt has doubtless incurred repeated risk from her communications with the Hedjaz, there is no evidence that even Egypt has been subjected to danger from cholera, at any time, through her direct maritime communications with more Eastern countries; let it be remembered that the Suez Canal has now been open for more than thirteen years; and let it further be noted that the present outbreak of cholera in Egypt is not on the line of traffic between Asia and Europe; and it will appear improbable, I think, that the use of the new highway will affect the course of cholera towards France and England. Still, it is not to be supposed that 1883 will find

us in every respect under the same conditions of human intercourse as 1865; and it is possible that some of the changed conditions may be such as to affect the opportunities for the migration of cholera. But, plainly, they are not worth speculating about, in view of our complete uncertainty whether those conditions for the diffusion of cholera which are independent of human intercourse are or are not to be the same in 1883 as in 1865.

3. *Precautions.*—"Quarantine," meaning by the word a system which professes to prevent the entry into a country of persons coming from another country until assurance is attained that no infection can be introduced by those persons, is not now regarded as capable of fulfilling its pretensions; and its least failure to exclude infection is seen to make the whole system irrational; its cost and its vexations unjustifiable. Accordingly, England, which long ago abandoned the system as of any avail against cholera, has now the consent of most European nations (as expressed by their delegates to the Vienna Conference of 1874) in preferring for the defence of her ports another system which, under the name of "medical inspection," aims at obtaining the seclusion of actually infected persons, and the disinfection of ships and of articles that may have received infection from the sick. The details of this system, as formulated for practical application in the ports and waters of England, are set forth in an Order of the Local Government Board of July 17th, 1873. Provision is there made for the detention of ships at appointed places; for the visiting and medical examination of ships and passengers; for the removal to hospital of persons suffering from cholera or suspected cholera, and for their detention there; for the speedy burial of the dead; for the disinfection or destruction of clothing and bedding; and for the purification of the ship and of articles therein. This order is at present operative. From a statement by Earl Granville, recently, I learn that it is proposed to reissue the order, though without change in essentials. It represents the system upon which we rely, in preference to quarantine, for the protection of our shores. For the last ten years the country has been thus prepared for the invasion of cholera, and the fact of this preparedness should be known. We have reason to hope that if cholera should enter England it will find fewer opportunities for doing mischief than at previous invasions. We are generally better provided with defences against a disease which spreads as cholera can spread. Some further precautions for use at the moment will doubtless be requisite; but it will be on our permanent sanitary works and procedure that we shall with most confidence rely.

The Sanitary Lessons of Indian Epidemics.

At a meeting of the Society on July 4th, 1883, Dr. Buchanan, F.R.S., President, Surgeon-General J. M. Cunningham, Sanitary Commissioner with the Government of India, read a paper on the above subject. He began by referring to the views he had expressed regarding cholera and other Indian diseases at a meeting held by the Society ten years ago, and proposed to inquire how far those views had been altered or confirmed by further experience. The field of observation in India is very large, and especially fitted, by its extent, the variations of race, and local conditions, for the study of epidemics. The large bodies of troops and prisoners scattered over this enormous area give exact data, which are supplemented by the statistics obtained regarding the general populations. These data deserve much more attention than they have hitherto received. India has contributed

largely to our knowledge in other fields, both of peace and war and in sanitary matters, also much may be learned from Indian experience; but in order to benefit by this experience it is essential that the history of disease should be considered not only from a local, but also from a general point of view. The facts must be most carefully collected; opinions must not be confounded with facts; all the facts must be collected, and not only those on one side; and solitary cases of epidemic disease must be studied with as much care as the many cases of the epidemic itself. Mere relation of time, a mere coincidence, must not be regarded as proof that the two events concerned stand to each other in the relation of cause and effect. It is essential that all evidence should be carefully weighed, and that undue value should not be attached to one class of facts on the plea that they embody positive evidence, to the entire exclusion of another set of facts which are considered as embodying only negative evidence. The theory which attributes epidemic or other diseases to importation is no explanation, but merely refers the question back to an anterior state of things—in other words, to the place from which the disease is said to have been imported. On inquiring into the causation of disease nothing must be assumed, neither the existence of germs nor anything else, but each step must be taken as the result of strict logical induction based on well-ascertained facts. These general principles are of vast importance in dealing with the difficult questions concerning disease, and especially concerning epidemic disease in India. The propositions that cholera is due to a germ originated in the delta of the Ganges, and that it is thence carried by human beings, rest on no such evidence; they are, on the contrary, opposed to the great facts now known regarding the disease in India: the general direction taken by cholera epidemics, the proved immunity of attendants on the sick, the small proportion of villages attacked even within the epidemic area, and others that might be mentioned. The only means of prevention of cholera is to be found in sanitary improvements and in removal from the locality where attacked, for its localization is one of the most peculiar characteristics of the disease. Experience tells much the same general truths regarding enteric fever, though this in India is in the main a disease of young Europeans new to the country; the importation and germ theory will not account for it. Enteric fever in India is the result of climate telling on constitutions unaccustomed to the strain, and favored as all diseases are by insanitary local conditions. It is to be classed with other forms of what is known as malarial fever. It is not necessary to find an entity to account for disease. The most powerful forces we know in the world, such as the wind, electricity, and steam, do not owe their powers to any entity that can be seen under the highest magnifying power. These are not mere theoretical views, they have a very practical bearing; they lie at the root of all sanitary progress. The commonly and too hastily accepted theories of germs and contagia have had the most disastrous consequences, causing much domestic misery by needlessly separating members of the same family at a time when their duty clearly lay in attending on their sick relatives and friends; they have also engendered needless alarm, which is most favorable to disease; they have caused the imposition of quarantines, which are but the natural outcome, and which are most harassing and annoying, and can be productive of no benefit; and they have caused the neglect of sanitary improvements, which are the only real preventives of disease. All this is very forcibly illustrated by what is going on in Egypt, where soldiers with

fixed bayonets are attempting to stay cholera; they might just as well attempt, with fixed bayonets, to stay the wind, the rain-cloud, or the thunderstorm. Dr. Cuninghame concluded by saying now was the time to see that our own house was in order, and that our sanitary condition was good.

In the discussion which followed, the President, Surgeon-General Murray, Mr. Edwin Chadwick, C.B., Brigade Surgeon J. B. Scriven, Surgeon-General De Renzy, and Sir Joseph Fayrer, K.C.S.I., M.D., took part.

OBSTETRICAL SOCIETY OF LONDON.

A MEETING of this Society was held on July 4th, Dr. Gervis, President, in the chair.

Hæmorrhage into Ovarian Cyst.—Dr. Robert Barnes exhibited a specimen of hæmorrhagic effusion into an Ovarian Cyst and the corresponding Fallopian tube.

Modes of Separation and Expulsion of Placenta.—Dr. Champneys showed two experimental demonstrations which he had used in lecturing since 1882, to illustrate: (1) The mode of separation of placenta (a) by contraction of placental site, as in ordinary labour, and (b) by expansion of placental site, as in placenta prævia; and (2) to illustrate the mechanical advantage of the edgewise presentation of the placenta.

Ovarian and Uterine Tumours.—Dr. Meadows showed a large Ovarian Tumour, together with the other ovary, the uterus, and a fibroid weighing six pounds and a half, which he had removed from a patient aged sixty-five.

Sloughing Uterine Fibroid.—The President showed a large Submucous Fibroid, which had sloughed suddenly and completely without any obvious cause or premonitory symptoms. There was also double pyo-salpinx, and one tube had ruptured, causing fatal peritonitis.

Pseudo-Hermaphroditism.—Dr. Chalmers exhibited the Genito-urinary Organs of a female child whose sex during life had been matter of doubt. The child had been shown at a former meeting of the Society.

Hydatiform Mole.—Dr. W. A. Duncan exhibited a Hydatiform Mole which he had removed from a patient aged fifty-one. The patient had suffered from hæmorrhage for three months previously, but had had no symptoms of pregnancy. The specimen was referred to a committee for further examination and report.

Ovarian and Uterine Tumours.—Mr. Knowsley Thornton showed a Soft Uterine Growth and an Ovarian Tumour removed from a patient aged fifty-six. The nature of the growth he hoped to report on at a subsequent meeting. He also showed an Ovarian Cyst highly Congested from Twisting of the Pedicle, which had been removed during acute peritonitis. He thought that in the specimen shown by Dr. Robert Barnes the hæmorrhage was probably the effect of twisting of the pedicle.—Mr. Lawson Tait agreed with Mr. Thornton as to Dr. Barnes's specimen. Such twisting mostly occurred in tumours growing from the right side, and depended on the action of the rectum.

Fibrinous Polypus.—Mr. W. S. A. Griffith showed a Uterus containing a Fibrinous Polypus, four inches long, formed of organized adherent blood-clot. There was no reason to think that recent pregnancy had occurred. The patient died from the bursting of a perinephritic abscess.

Hypertrophied Nympha.—Dr. Fancourt Barnes showed a Hypertrophied Nympha which he had removed.

The Obstetrics of the Kyphotic Pelvis.—This paper,

by Dr. Champneys, was then read. An analysis was given of thirty-two labours in twenty women, including three labours in a patient of the author's, the last labour having been carefully observed. An analysis and a table were given stating the presentation, change during labour, measurements of fetal skull and pelvis, operative measures, moulding of fetal skull, result to child and mother. The general remarks of other writers on the subject were summarized. The general conclusions at which the author arrived were the following:—That vertex presentations, and especially right occipito-iliac positions, are unusually frequent; deep transverse position is common, posterior rotation not uncommon. The comparative frequency of occipito-posterior positions is probably due (as explained by Hoening) to the obstacle to forward rotation in third positions, which are very common. The head sometimes emerges from the ligamentous pelvis transversely or nearly so, and entirely posterior to the tubera ischii. The analogy to the "extra-median" position was pointed out. The well-known looseness of the pelvic joints in this pelvis, probably assisted this by the nutation of the sacrum. Spontaneous premature labour is not uncommon. The immediate fetal mortality in the published cases was 40·6 per cent., the maternal 28·1 per cent.; but the author thought this estimate probably too high, as slight cases were not recorded. The conclusions as to treatment and prognosis were:—1. In a first labour, if the head present, wait and act according to circumstances. This implies forceps craniotomy, or Cæsarian section, which should always be considered in the above order. 2. If the head present, never turn. 3. In subsequent labours, where the history of the first labour seems to indicate it, premature labour may be induced with good hope. 4. No known measurements give us any sure indication for forceps, turning, Cæsarian section, or the date for induction of premature labour. 5. The mobility of the pelvic joints implies a prognosis always more favorable than measurements would lead us to suppose. 6. Probably in many cases the head entirely neglects the anterior half of the pelvic outlet, and emerges from it transversely, or at most obliquely, antero-posterior emergence being the exception. 7. Each succeeding difficult labour increases the liability of the uterus to rupture, as in other forms of pelvic distortion.—Dr. Roper remarked that the mechanism described by Dr. Champneys resembled that of labour in the lower animals, in which there was no pubic arch, and the fetus always passed behind the ischial tuberosities. This diminution of curve in the pelvic axis somewhat lessened the difficulty of labour. In cases of kyphosis the vertical capacity of the abdomen was diminished; hence the uterus was thrust forward, and pendulous belly was common, and led to difficulty in the entry of the fetus into the brim. He described a case which he had seen. In these cases the deformity of the outlet obstructed delivery more than that at the brim.—Dr. Herman agreed with the author that the published cases probably contained an undue proportion of difficult labours.—Dr. Champneys thought that pendulous belly was produced by anything which shortened the abdominal cavity.

A Note on Uterine Myoma; its Pathology and Treatment.—This paper, by Mr. Lawson Tait, was then read. The author thought that the word "myoma" should entirely supersede the incorrect term "uterine fibroid." The growth of ordinary myoma was limited to the period of sexual activity, was influenced by the menstrual function, and probably its ultimate cause would be found in some disturbance of the nervous body which gov-

erned that function. The presence of a myoma indefinitely delayed the menopause. Menstruation and ovulation he thought were completely independent functions, having perhaps a community of purpose. Removal of the ovaries often did not affect menstruation, but removal of the tubes nearly always did so. But in one case in which he had removed both ovaries, tubes, and part of the fundus uteri, menstruation continued for more than a year. He deprecated the triple subdivision of myomata into submucous, intramural and subperitoneal. For pathological and surgical purposes he proposed a new subdivision into the nodular and the concentric. The latter consisted of a uniform hypertrophy of the muscular tissue of the uterus, in the midst of which the canal lay centrally; the tissue of this form was loose, and usually very oedematous. Of the nodular myoma he proposed two subvarieties, the simple and the multinodular. He believed that each nodule was seated on a central arterial twig, and that its growth was endogenous, the older tissue being on the outside. The dependence of such growth on menstruation was proved by the fact that arrest of menstruation stopped the growth, or even caused the complete disappearance of such tumours. This had been in several cases brought about by the removal of the tubes only. He had treated fifty-four cases of uterine myoma by removal of the uterine appendages, with three deaths, a mortality of 5.5 per cent., a striking contrast to the results of hysterectomy. Of these fifty-one, in thirty-eight the results had been carefully followed, and were everything that was to be desired. In three the tumours were or became malignant. In three others the tumours continued to grow, although menstruation had been arrested. The author suspected that these were either fibro-cystic or myoma of the concentric variety, in neither of which forms was the removal of the uterine appendages useful.—The President was hardly prepared to accept Mr. Tait's classification; but it was not necessarily antagonistic to the one in common use. He agreed with Mr. Tait as to the delay in the menopause in these cases. He would like further evidence as to the sole or even large influence of the tubes in the phenomena of menstruation.—Dr. Herman had published a case in which the symptoms of a fibroid polypus first appeared sixteen years after the menopause. The history of patients after operations like those of Mr. Tait was of great importance, for patients not benefited often did not return to the operator, and he therefore was apt to get a too favorable impression of the results.—Dr. Dewar asked if Mr. Tait was careful to tie the uterine artery, and whether removal of the tubes, leaving behind the ovaries, was not dangerous. He had seen one case in which the uterine appendages had been removed, and hysterectomy was subsequently required on account of hæmorrhage.—Dr. Meadows preferred the present classification of fibroid growths to that suggested by Mr. Tait, as being founded on clinical characters and of great practical value for diagnosis and treatment. He believed that the ovaries, and not the tubes, were the prime movers in menstruation. In one case he had removed the ovaries and left the tubes, and menstruation ceased. He thought there were many exceptions to the rule that uterine fibromata ceased to grow after the menopause. Notwithstanding the high rate of mortality which attended hysterectomy, he preferred it to removal of the ovaries.—Mr. Lawson Tait said that cases of growth of apparent uterine myomata after the menopause needed most careful examination. Occasionally removal of the ovaries arrested menstruation, but this was the exception. He had

never, knowingly, tied the uterine artery; and it would be very difficult to do so.

OPHTHALMOLOGICAL SOCIETY OF THE UNITED KINGDOM.

Annual General Meeting.—Sympathetic Ophthalmia.—Hemiachromatopsia.—Foreign Body embedded in the Fundus Oculi.—Anomalous Distribution of Retinal Arteries.—Congenital Ptosis.—Nævus.

The annual general meeting of this Society was held July 6th, Mr. W. Bowman, F.R.S., President, in the chair. The Treasurer, Mr. Streetfield, made his annual statement. An alteration in the bye-law relating to subscriptions was proposed from the chair and carried. The ballot for officers and Council was taken.

The President briefly addressed the meeting, and said that the Society had passed through its third session in a satisfactory state. Twenty-two new members had been elected, fourteen of these being metropolitan, three from the colonies or dependencies, and five non-metropolitan, but within the kingdom. Two members had died—viz., Mr. Critchett and Mr. R. W. Lyell. The Society had already expressed its sense of the great loss it sustained in the demise last autumn of their eminent and esteemed colleague, Mr. Critchett; and in Mr. Lyell the Society had been deprived of a member whom they had hoped would have added much to the value of its records. The total number of ordinary members is now 176. There had been eight meetings, one being an extra meeting for the adjourned discussion on Eye Symptoms in Spinal Disease. The total number of communications read this session was sixty-six, including several papers of much scientific value. The special subject opened by Dr. Gowers at the June meeting gave rise to a fair discussion and to the contribution of a considerable mass of facts. The discussion was of much value as it stood, but its greatest use would doubtless lie in the stimulus it would give to more exact clinical and pathological research in regard to certain specified points and problems.

Mr. Simeon Snell (Sheffield) read notes of a case of Sympathetic Ophthalmia, operation on the Exciting Organ, with recovery of practically perfect Vision in both Eyes. The patient, a man aged thirty-six, on Oct. 6th, 1882, ran a packing needle into his left eye. He came first under observation on Oct. 20th; then he had prolapse of iris, wound in lower and inner sclero-corneal junction, encroaching on ciliary region.—Nov. 3rd: "A mistiness" complained of two or three days since in front of right eye; to-day plastic iritis; pupil hardly acted upon by atropine.—5th: Condition worse, and next day still more aggravated.—6th: Prolapse incised, and as much iris as possible excised. Very little was removed, and that only by piecemeal, as it was incorporated in tissues. The incision was prolonged on either side in the sclerotic, just behind the corneal junction (sclerotomy). Next day there was an improvement; the pupil soon dilated and the iritis subsided. The prolapse in the left eye has disappeared.—19th: There appeared a little iritis, and perchloride of mercury was ordered internally, recovery soon taking place. In a few weeks he resumed work.—April 13th, 1883: In either eye V = 20-20; and he is able to follow his employment as well as formerly. Mr. Snell remarked on the satisfactory result obtained in both eyes; on the anxious nature of cases in which in the exciting eye vision still remains good; and on the scant reference generally

made to means for preserving the injured as well as the sympathizing eye in such cases. He thought the case he related instructive and encouraging.

Mr. Swanzy (Dublin) read notes of a case of Hemichromatopsia in a gentleman, aged seventy-seven, who in November last had a slight attack of cerebral apoplexy, which rendered him unconscious for about twelve hours, and from which he completely recovered in the course of a few days, except for some defect in vision and a confusion of ideas when he made any unusual mental effort. He had not even for a short time any hemiplegia, affection of speech, or other paralysis. Five months later Mr. Swanzy was consulted, the patient's chief complaint being a difficulty in recognizing his friends even when near to them. In each eye H. 1.5 D. V=6-12. In the left eye a slight peripheral opacity of the lens, but in all other respects the eyes were organically sound. The defect in vision could only be accounted for by senile changes in the media and retina, but this comparatively slight defect was insufficient to explain his difficulty in recognizing people, which Mr. Swanzy was inclined to regard as a disturbance of a cerebral function. Examination with the perimeter displayed a slight homonymous defect in the right upper quadrant of each field. The patient complained that his color vision had not been so acute since the attack in November, but yet he was able to perform Holmgren's tests with accuracy. When the fields were examined with colored wools, Mr. Swanzy found that the left side in the field in each eye was totally color blind, while with the right side colors could be distinguished, although in an area very much and concentrically contrasted. (Charts exhibited.) This, and those similar cases (Landolt's, Samelsohn's, and Bjerrum's) clearly show that the nervous elements in which the power of perception of color resides are situated in the brain, and not in the peripheral visual apparatus, and that the color centre in the brain is distinct from that for the form sense and for ordinary light perception.—Mr. B. Carter observed that there were cases on record which hardly confirmed the author's view. He had lately seen a gentleman who complained of lowered vision, and found that it was 8-40 in the right eye and 8-50 in the left. In the latter there was a color-scotoma in the lower part of the field, reaching ten degrees on both sides of the fixing point. There were no ophthalmoscopic changes, and he attributed the defect to tobacco.—Mr. McHardy mentioned the case of a man who became suddenly color-blind, complaining one day that he was disgusted with the color of the meat he saw in butchers' shops. He was the subject of albuminuria, and died suddenly from apoplexy.—The President said the case was interesting, because it is known that loss of half the field is due to brain disease, and here there was defective color sense in one-half; so it might be concluded that it depended on a cerebral lesion.—Mr. Swanzy, in reply to a question by Mr. Nettleship, said he had taken great care to test the centre of the field, because of the fact that in ordinary hemianopia the dividing line usually passed a few degrees to one side of the point of fixation. In this case the color-scotoma, however, seemed to pass precisely through the centre.

Mr. J. E. Adams related a case of Foreign Body (a piece of steel) embedded in the Fundus near the Macula, with almost perfect vision. The patient, a smith, aged twenty, was struck in the left eye in November, 1881, by a chip from an anvil. It wounded the sclera, choroid and retina on the outer side, penetrating the vitreous and lodging in the fundus above and to the outer side of the macula. The body was covered by remains of lymph and pigment, and some striae denoted the

remains of hyalitis. An attempt was made to extract the piece of metal by introducing the pointed electro-magnet, though the large instrument was held close to the eye for some minutes without result. For some hours after the injury he could not distinguish light from dark, but since then vision has steadily improved, and is now normal. A similar case is recorded by Mr. Snell in the Royal London Ophthalmic Hospital Reports, Vol. IX.—Mr. Snell said that in his case the foreign body entered a little beyond the sclero-corneal junction. Vision shortly after the accident was 20-50, and subsequently the patient could read Jaeger No. 1. Since then he had seen a similar case with less good result. The particles passed through the cornea and lens and lay below the disc. At the end of two years the lens became opaque. Knapp has collected twelve recorded cases, and mentions the possibility of applying the electro-magnet, but he should not advise its use.—Mr. Adams Frost saw a case with Mr. Waren Tay. The lens escaped injury and the media were clear. A glistening body could be seen just at the macula. Vision was fairly good, and there was no inflammatory symptoms. The electro-magnet was not used.

Mr. J. E. Adams exhibited an Ophthalmoscope for artists, in which the mirror is worn in a band on the forehead, so that the hands are left free for drawing.—Mr. McHardy alluded to the liability to fatigue, with tenderness over the median nerve, to which ophthalmoscopic artists were subject, and thought that artists would appreciate the instrument.

Mr. J. B. Story (Dublin) communicated notes of a case of Anomalous Distribution of the Retinal Arteries, and exhibited a drawing of the condition. In the fundus of the right eye the superior nasal artery divided at once into two branches, the lower of which ran horizontally inwards for a short distance, and then gave off a branch which ran downwards showing several curves, and finally ended in the descending division of the artery near the disc without undergoing much change in calibre. Careful search failed to detect any direct communication between this arterial system and the central artery. It was suggested that the superior nasal artery of the retina had been occluded by an embolus or thrombus in very early life, and that a collateral circulation was established by the dilatation of capillary vessels connected with the inferior retinal artery.—Mr. McHardy said the case was very analogous to one which he had seen a year ago in a young American. The appearance suggested aneurismal varix. The case was seen also by Mr. Bowman, Mr. Carter, and Mr. Nettleship.

Mr. Gunn exhibited a girl, fifteen years of age, who was the subject of congenital drooping of the left upper eyelid with contracted pupil on the corresponding side, but in whom the drooping lid was raised whenever and only when the corresponding external pterygoid acts on the jaw.—Dr. Cholmeley pointed out that the eyelid was not materially lifted unless the chin was turned to the right.—The President suggested that if it was deemed necessary to improve the girl's appearance, it might be well to close a little the outer palpebral canthus of the opposite eye. The following gentlemen were nominated to serve on a committee to report on the case: Dr. Gowers, Dr. S. Mackenzie, Dr. Abercrombie, and Mr. Lang.

Mr. Mark J. Symons showed for Mr. Lawson a case and drawing of Disseminated Choroidoretinitis, with very peculiar white raised patches near the disc, in a man twenty-three years of age, who contracted syphilis thirty months ago.

Mr. Power exhibited a young woman twenty-

three years of age, with a patch of morphaea on the left upper eyelid.—Dr. Mackenzie remarked that if left alone the patch would eventually disappear.

Mr. Hulke exhibited a drawing from a case of Cysticercus in the Vitreous Humour. The child was afterwards in St. Bartholomew's Hospital, under Mr. Bowater Vernon.

Mr. A. H. Benson (Dublin) showed a drawing of numerous Aneurisms on the Retinal Vessels, both veins and arteries. There was no increase of tension.

Dr. Horrocks exhibited a case of Facial, Conjunctival, and Retinal Nævus. The patient was a girl, aged nine, who had been subject to fits since birth, and she was hemiplegic on the left side. The right side of the face, including the skin of the eyelids and forehead, was covered with a nævus giving a port-wine stain appearance; the conjunctiva was also affected. On ophthalmoscopic examination the retinal veins of the right eye were seen to be very tortuous, those on the left being normal. Owing to her defective intellect, nothing satisfactory could be elicited as to vision, but as far as could be made out she saw equally and well. Dr. Horrocks pointed out that the tissues in which the vascular dilatations occurred were epiblastic structures, suggesting the possibility that the vessels of the pia mater on the right side were similarly affected, thereby having something to do with the left-sided fits.—Dr. S. Mackenzie said that a few years ago Dr. Allen Sturge showed at the Clinical Society a case in which there was a nævus on one side of the face and paralytic symptoms on the opposite side of the body; and he argued the possibility of there being the same condition in the brain as in the skin. Dr. Horrocks' case lent some support to that view. At the same time the condition of retinal vessels described had been met with on both sides, without any particular symptom.—Mr. Nettleship said that in Dr. Sturge's case there was nævus of the sclerotic also, and the affected eye was larger than the other.—Dr. Horrocks suggested that in cases of marked tortuosity of the retinal veins the condition might be due to similar foetal disturbance as that which sets up cutaneous nævus.

Mr. Story (Dublin) showed a portable arrangement for ophthalmic ointments.

This closed the business of the evening, and Mr. Brudenell Carter proposed a vote of thanks to Mr. Bowman for the services he had rendered to the Society during his three years' tenure of office as President. The fostering care and devotion to the interests of the Society shown by Mr. Bowman would be remembered whenever the time or occasion offered to review his honorable career. He trusted that Mr. Bowman would still be enabled to attend their meetings; and in leaving the chair he would take with him their grateful sense of the dignity and impartiality with which he had discharged the duties of his office. The vote was carried by acclamation.

Mr. Bowman said the very kind words which Mr. Carter had addressed to him were most unexpected, and their reception by the meeting most gratifying. His mind was led back by them to the condition of things which prevailed when he first began to study in those fields that now interested them all so much. How comparatively imperfect and elementary was our knowledge then of the structure and physiology of the eye and of its diseases, and how very inadequate in general were the methods of treatment. For the subject had hardly emerged from that early stage when it was dealt with either on the most general lines or on those of a narrow specialty. How different was the case now. No department of the medical art

has shown such splendid progress, at so rapid a rate, and with such admirable results. It had been a great pleasure to him during a great many past years to follow these advances, and perhaps to bear some very small part in promoting them, and particularly to have been lately permitted as their first President to share with others in the happily conceived design of bringing together in one Society all or most of those engaged in ophthalmic practice and the kindred side of the medical art throughout the United Kingdom and its great colonies and dependencies; of thus uniting them for the pursuit of their profession with greater zeal and higher aims, and, by encouraging the production, discussion, and record of all that pertains to ophthalmology, to make permanent additions to the common stock of knowledge. He thought the result had been very successful, and that they were to be congratulated on the stage at which ophthalmic practice had arrived in this kingdom. For himself he could claim but a very slight share in the work of the Society; the credit belonged rather to those who first initiated it, and they were particularly indebted herein to the first two secretaries, Dr. S. Mackenzie and Mr. Nettleship, and to Dr. Brailey, as well as to all those gentlemen, especially on the medical side, who had co-operated with them. For it was one of the great advantages of the Society that it had brought into practical union those who study eye disease from the medical side and those concerned in the special practice of ophthalmology. It represented the inherent unity of the ocular organ with the whole organism of which it was a part; and the necessity of studying it always in the light of this relationship as well as in view of that wider relationship which it bears to all the organic life upon the globe. To have brought physicians and surgeons together on this common ground was already a great and manifest gain. He trusted they would always continue to hold up ophthalmology in the interest of medicine at large as that department of the medical art in which exact knowledge was most attainable, and the application of it for the prevention and alleviation of disease best exemplified. Mr. Bowman concluded by stating that he should be most pleased to continue to attend the meetings of the Society whenever possible.

ACADEMY OF MEDICINE IN IRELAND.

Spontaneous Dislocation of the Hip.—Spinal Injury and Muscular Atrophy.

At a meeting of the Surgical Section held on March 9th, Mr. Kendall Franks read a communication on Spontaneous Dislocation of the Hip, illustrated by two cases which he had himself observed, and of which casts were exhibited. A child, aged five, was admitted into the Adelaide Hospital in January last. She had been confined to bed since the summer of 1882, suffering from "acute disease of the left hip-joint." The acetabulum had chiefly suffered, and the head of the femur had probably passed partially through it, and in that position ankylosis had taken place. An abscess which had formed burst into the vagina, and healed up. The limb remained permanently fixed in a semi-flexed position, abducted and rotated outwards. The child had been chiefly lying on this side, the right leg flexed, adducted, and rotated outwards, so that the knee lay behind the knee of the diseased limb. In August last, as she was being turned in bed by the nurse, a remarkable protuberance was seen behind the right anterior superior spine of the ilium. The child was questioned about it, but could not give any account

of how it occurred. It gave rise to no pain. This protuberance was caused by the great trochanter, the head of the right femur having slipped out of its socket, and being easily felt on the dorsum of the ilium. No alteration in the parts has since taken place. The second case illustrated a dislocation of the hip, taking place during an attack of acute rheumatism. A girl, aged fifteen, was admitted into the Adelaide Hospital on Oct. 10th last, suffering from necrosis of the left tibia. She presented a well-marked dislocation of the right femur on to the dorsum of the ilium, the limb being shortened to the extent of $3\frac{1}{4}$ in. In May, 1879, she had an attack of acute rheumatism, from which she completely recovered. In the following February—that is, two years ago—she was attacked again with the same disease, which kept her in bed for ten weeks. The right hip-joint and the right shoulder were the parts chiefly affected. To alleviate the pain pillows were placed under the hip and knees. When she tried to get out of bed after the disease had subsided, she found the right limb considerably shortened, so that she could only reach the ground with the ball of the foot. The right hip was deformed, and she now presents all the characteristic signs of a well-marked dislocation. The head and neck of the bone can be easily identified in their new position, and feel quite smooth and healthy.—Mr. Stokes instanced a remarkable case formerly under his care in the Richmond Hospital, in which a fall was apparently the exciting cause. The patient fell down stairs, sustaining a very severe injury, but he did not apply for advice till a fortnight had elapsed, when it was found he had sustained a dislocation on the dorsum of the ilium, which was, with very little difficulty, reduced by manipulation. Next day, dislocation again occurred, and was reduced; but luxation recurred three or four days in succession. He suggested in explanation that the fracture of the rim of the acetabulum had taken place originally, and a portion of the bone was driven away from its normal situation at the time the luxation recurred.—Mr. Bennett thought that too much importance was attached to the term “spontaneous.” All pathological dislocations were spontaneous. A more important division would be as to whether the dislocations were complete or incomplete. The term “spontaneous” was a mistake for want of observation. In the deformity in question he would not be surprised if the bones were still intact, but altered in shape.—Mr. Franks, in reference to Mr. Bennett’s criticism of nomenclature, confessed he had had difficulty in choosing a title for his paper. Perhaps it would have been better had he described the dislocations as simple spontaneous dislocations to distinguish them from disease of the articular surface. He agreed, however, with Malgaigne, that the best line of distinction to draw was between dislocations due to simple relaxation of the ligaments without any disease of the ends of the bone, and cases in which there was caries or some other disease on the head of the bone. Dislocations that occurred from distension of the ligaments formed a distinct group.

Dr. R. McDonnell brought before the section notes of three cases of Injury of the Spine, followed by Progressive Muscular Atrophy. In all three cases there was little, if any, loss of sensibility. The patient was sensitive to tactile and thermic impressions. The wasting of the muscles was rapid and set in early after the injuries. The character and appearance, as well as the marked degree in which individual muscles were attacked, showed, in the author’s opinion, that muscular atrophy in these cases depended upon the same causes which produce individual muscular

atrophy in infantile paralysis and paralysis of the Duchenne-Arun type—viz., myelitis affecting the large motor nerve cells in the anterior cornua of the spinal cord.—The President inquired what were the conditions present in the case that recovered.—Dr. Swan, referring to the same case, asked the author if he believed that there was generation of the cells in the anterior horns.—Mr. Wheeler mentioned a well-known case that was in the City of Dublin Hospital, under the care of Professor Purser, suffering from Cruveilhier’s palsy. The patient was a tall, gaunt man, who used to stand at Baggot-street Bridge, and had been driver of the Wicklow coach. His upper extremities were only held to his trunk by the levator anguli scapulae muscles, so that the posterior superior angles of his scapulae were pulled up close to his ears. He stood with his body thrown forwards, to prevent his abdominal viscera from falling forwards, as all the abdominal muscles had disappeared. The palsy apparently originated from injury. He fell and hurt the back of his neck and spine. From the cast shown by Dr. McDonnell it seemed that the flexor brevis abductor and opponens pollicis muscles were very much wasted. He asked, could Dr. McDonnell assign any reason why the flexor ulnaris muscle and other muscles were not wasted in the same proportion, and if he had made observations in similar cases of the condition of the nerves down the forearm whether their motor fibres were altered. With regard to Dr. McDonnell’s second case, it appeared to him (Mr. Wheeler) that the trophic cells were not engaged, but only the connective tissue elements, and when it returned to its normal condition the temporary influence it exercised on the cells ceased.—Dr. McDonnell, answering Mr. Wheeler, first as to how the particular muscles atrophied, said in all of those that belonged to the group he was speaking of it commenced in the spinal cord. If a group of those cells disappeared, it might be laid down as certain that the muscle corresponding with that group of cells would also disappear, and the nerves leading to that would wither away. In those cases which he had examined the nerve-fibres in the roots were found to be atrophied. The question was naturally asked, “Might it not begin in the muscle?” or, as Cruveilhier put it, in the nerve-root, or in the trophic cells? Years ago he had himself asked Lockhart Clarke if he had had opportunity of examining cases in which, long after amputations, those cells had not been called into use, and whether for want of use they had become atrophied. It appeared that in fifty or sixty cases which he had examined in Greenwich Hospital the cells in the spinal cord were found to be right. Evidence had been accumulated to show that the disease really began in the nerve-cells and spinal cord.

Hæmophilia.—Muscular Spasms.

A meeting of the Medical Section was held on March 16th, Dr. Wm. Moore, President of the Section, in the chair.

Dr. McDonnell exhibited a case of Hammer-cramp, and Dr. Storey a case of Hæmatrophia Facialis.

Dr. Fraser read a paper mentioning some instances of Serious Bleeding following trifling injuries, and then described two cases of Sudden Death from Sanguineous Apoplexy occurring in individuals who had previously suffered from bleedings of the nose, lungs, etc.—Dr. Henry Kennedy related a fatal case of purpura in which the post-mortem examination revealed an extensive effusion of blood over the surface of the brain; and he referred to Latour’s observations on hæmorrhage.—

Dr. Cox referred to a gentleman the subject of hæmorrhagic diathesis, in which a chill appeared to be invariably the exciting cause of the hæmorrhage. In this case there was a well-marked family history of the diathesis.—The President mentioned a case of an old lady who suffered from severe epistaxis, and shortly afterwards became completely demented.—Dr. Fraser, in reply, said he introduced the first two cases merely to show that he was not overlooking the subject of hæmorrhagic diathesis. In such cases the blood was almost water; but in the cases of the gentleman pointedly alluded to, he never saw better clotting blood. The hæmorrhage in his case was not produced by a chill, but he appeared to form more blood than was required, and this was eliminated by nose, lungs, or kidney.

Dr. R. McDonnell showed to the Section a patient, a young man, twenty-two years of age, whose right arm was subject to muscular spasms. The patient was a nailer by trade, and had been since he was eleven years old more or less hard at work at this occupation. The spasmodic jerkings of the muscles, which interfered with his occupation, began about seventeen months ago, and after the first three months became so violent that he had to give up work altogether. The case was one of functional spasms unaccompanied by pain, and is an affection very similar to writer's or scrivener's cramp, although all the muscles supplied by the brachial plexus seemed to be affected, and those around the shoulder-joint, especially the great pectoral, seemed to be most so. The treatment consists in regular, orderly, rhythmical movements of the limbs, as was so successful in a very similar case reported by Dr. G. V. Poore in the *Practitioner*, Sept., 1872.—Dr. Foot said this man had been under his care for a considerable period, during which time there was a marked improvement in his symptoms. He did not consider it at all a wonderful case. He thought it was analogous to other cases, such as telegraphists, milkers, violin and pianoforte players. He was not aware that it differed from several cases recorded by Dr. Frank Smith, of Birmingham, which was a centre of nail-making. He never thought there was any approach to chorea, as when in bed the muscles were perfectly quiet.—Dr. Henry Kennedy remarked that Dr. Harley had succeeded in curing similar cases by huge doses of succus conii, two ounces at a single dose.—The President and Dr. F. C. Moore having also taken part in the discussion, Dr. McDonnell replied. He said that there were two points raised by Dr. Foot in reference to the case. First, there was no difference of opinion as to the nature of the case, which belonged to the category of scrivener's palsy, but differed from the tremor in piano players, etc. His case also differed from those of Dr. Frank Smith in not having general paralysis. Dr. Smith's cases bore no relation whatever to scrivener's cramp or hammer cramp. The second point was that Dr. Foot did not seem to think that the case belonged to chorea, because the patient was quiet at night. But so far as his (Dr. McDonnell's) experience went, in any except the most exaggerated case of chorea the movements were entirely stopped during sleep.

The Third Stage of Labour.

At the meeting of the Obstetrical Section, on March 30th, 1883, Dr. R. Henry read a paper on the Importance of the Third Stage of Labour. He commenced by pointing out the various risks, immediate and remote, to which the improper performance of the third stage of labour exposed a

woman. These risks would be minimized by a suitable conduction of this most important period of labour. To arrive at any just conclusion on this subject, it was necessary, in the first place, to study nature's methods in effecting the separation and delivery of the placenta and membranes, by the conjoint action of tonic and clonic contractions moulding the placenta, as had been described by Dr. Matthews Duncan, or in the different way described by Schultze. In the author's experience both these methods had been observed, a lateral attachment of the placenta being Duncan's, while a fundal or nearly fundal one would give Schultze's. The former was the more common method. Dr. Henry quoted Denman, Smellie, Collins, and others on the question of manual interference in the third stage. In 1786 Dr. Joseph Clarke had advised the practice of "pursuing with a hand on the abdomen the fundus uteri in its contractions until the foetus be entirely expelled, and afterwards continuing for some time this pressure, to keep the uterus, if possible, in a contracted state." This practice had been largely adopted in Dublin. Dr. Henry adhered to it, believing that in modern practice undue haste to press off the placenta was constantly exhibited. He kept his hand over the uterus during delivery and subsequently, but forbore pressing or actively supporting the uterus until it had itself commenced to contract clonically. Assistance should only be given with the clonic contractions. A safe and permanent contraction following the expulsion of the secondaries might in this way be usually secured in from ten to twenty minutes. The chief error at present consisted in mistaking constant irritation for support of the uterus.—The President said the paper raised several questions of deep interest—viz., as to the time at which the placenta should be removed; as to the danger on the one hand of being too precipitate, and on the other of leaving in the placenta too long; as to how far hæmorrhage was sometimes induced by a too speedy removal, and at other times by leaving the placenta too long in the uterus; and also as to the danger of leaving in portions of the membranes.—Dr. Harley objected altogether to premature pressure over the fundus of the uterus for the purpose of pressing off the placenta. He also objected to exercising pressure on the cord at any period.—Dr. W. J. Smyly stated that in the Strassbourg Hospital, where the patients were, as a rule, left to nature during the third stage of labour, it had been observed that the placenta was most frequently expelled in the manner described by Schultze. He believed that Credé's method of exciting the uterus to contraction had been confounded with the hasty expulsion of the placenta. Credé himself never advocated the immediate expression of the placenta, but rather the immediate excitation of the uterus by irritation and friction through the abdominal walls, and then usually with the third or fourth contraction the expression of the after-birth. The immediate expression of the placenta was very liable to be followed by the retention of the membranes and post-partum hæmorrhage.—Dr. Macan said that since the time of Hippocrates there had been ebbs and flows of opinion as to whether expulsion of the placenta should be left entirely to nature, or should be immediately effected by the accoucheur either by passing the hand into the uterus, as the older authorities recommend, or by the more modern treatment of expression. Hence he thought that a happy mean between these two methods was probably the best way, for if the uterus was well contracted, there need be no fear of hæmorrhage, and therefore no cause for hurry; while if the uterus was relaxed with hæmorrhage, the removal of the placenta tended certainly to increase the hæmor-

rhage by removing all pressure from the mouths of the uterine sinuses, unless the means used to remove it at the same time caused the uterus to contract. The great advantage claimed at the present day by the adherents of the plan of leaving the whole process to nature, was that a much larger proportion of the decidua came away with the placenta than when the placenta was immediately removed. When two such authorities as Dr. Matthews Duncan and Professor Schultze differed as to the mechanism of the separation and expulsion of the placenta, it was pretty certain that there was more than one way, and that both their views were probably right. If they adopted the expression plan, which might, he thought, be called "the Dublin method," they should be careful not to allow the placenta to be suddenly expelled on to the bed; for a sudden strain was thus put on the membranes, and a portion might readily be torn off and left behind in the uterus. This had been looked on as a very serious accident. But he was inclined to think that the mere presence of a portion of the membranes in the uterus for some days after delivery could not be looked on as dangerous unless air had been allowed to enter and set up decomposition. He also thought that it was very often during the efforts made to remove a piece of retained membrane that the air was caused to enter the uterus. He had often seen a piece of the membrane expelled some days after delivery without being accompanied with the slightest fetor or giving rise to the least fever. Indeed, it seemed to him probable that, in hospital practice at least, the danger from retention of a portion of the membrane was less than the danger of infection from the hands of the operator in his efforts to remove it. He always waited a quarter of an hour before attempting to press off the placenta, and considered that light friction over the fundus with the tips of the fingers was a much more powerful method of inducing contraction than merely holding the fundus in the hands.

CAMBRIDGE MEDICAL SOCIETY.

Hysteria.—Genu Vulgum.—Tetanus.

At a meeting held on June 1st, 1883 (Mr. James Hough, Vice-President, in the chair), Dr. Ingle read the notes of a case of Hysteria in a Boy. The patient, aged ten, well developed, but rather strumous looking, the eldest of five robust children, was first seen on May 1st, 1881. He had been complaining of headache and sickness and was restless and irritable. He kept in bed with the room darkened and his eyes shaded from the light by his arm; his lids were closed but trembled suspiciously. The thighs were flexed over the belly and the legs on the thighs. He took no notice of what was said to him and would scarcely answer a question. He had taken nothing but water for some days and now refused that. His temperature was over 100°; the tongue coated; bowels obstinate; and the urine loaded with phosphates. The bowels acted freely after an aperient was given, there was no trace of worms, but his condition was not improved and he showed extreme sensibility to sound as well as light. He remained in the same state for a fortnight, when he was seen in consultation with Dr. Latham. He continued to get worse, refused to sit up, and at night disturbed the household with screaming and incoherent talking. His bowels were said to act only once a week. Till now he had been nursed by his mother; her attendance ceased on July 6th, and he somewhat improved, but he became worse when she returned, and was re-

moved to the hospital. On returning home in October he resumed his old condition, and his mother asserted that he now had no relief from the bowels, passed no water, and positively refused nourishment of any kind, to all of which she seemed to give credence. The father, however, determined to clear up the mystery, and for this purpose concealed himself under the bed whilst the boy was asleep. It appeared that the boy got out of bed and went into an adjoining room, where, after loosening a plank in the floor, he removed it, and made use of the hole as a urinal. The ceiling below was found to be discolored, and there was evidence that this trick had been continued for some while. It was also discovered that the boy managed to conceal biscuits in his pillowcase, to satisfy his hunger. Soon afterwards the boy recovered. Dr. Ingle thought the case of interest from its occurring in a boy quite young, and of retiring disposition. There was no apparent cause, nor was there anything to gain by assuming illness or anything unpleasant to escape. At the commencement it had been mistaken for a case of incipient disease of the brain, but after a time there was no doubt that it was mainly hysteria.—Dr. Latham remembered the case. At first the symptoms were rather like those of early tubercular meningitis, but after some weeks the nervous systems were exaggerated. The boy was under his care in the hospital, and was occasionally fed with the stomach pump and his urine drawn off with the catheter. He improved under galvanism.—Dr. Bradbury related a case of a somewhat similar nature in a boy, aged sixteen, who had been overworked. Peculiar nervous symptoms came on simulating spastic paraplegia; the urine had to be drawn off with the catheter, and there was almost complete insensibility. Recovery took place after a time.

Mr. Wherry read a paper on the Treatment of Genu Vulgum, and showed his frame, in which the patient stood upright with his back against a door or wall; when the knees were slightly bent a disc of cushioned cork could be placed between, so that the upright position being resumed the knees were forced apart and so kept. The disc was useless without the frame which kept the toes and heels together. The sitting cross-legged tailor-fashion was also useful. A growing boy could do his lessons in this position sitting on a large cushion on the floor like a Turk for hours daily without discomfort. For the treatment of genu vulgum in young children home-made splints were exhibited, constructed on the same principle as described by Mr. Bernard Roth. The limb from the groin to the ankle is first swathed in cotton-wool, then firmly bandaged with the usual plaster-saturated crinoline bandage, an outer straight wooden splint placed between the layers of the bandage, and the limb thus kept in position; a layer of strong gum is now applied, and the whole covered with bed ticking cut to pattern. The next day the hard case is to be cut up along the front of the splint with vine-dresser's shears, and the cotton-wool carefully cut with scissors. When lined inside with wash-leather and hooks placed along the outside of the edges for lacing, it forms a capital case, and was well borne by a child who had resented other apparatus. It is both cheap and successful.

Dr. Ransom related a case of Tetanus terminating in recovery. J. B., aged sixteen, strong and well grown, on March 24th, 1883, ran a garden fork prong through his left great toe. His mother applied common salt first, and afterwards bread-poultice. On April 5th, the toe being healed, symptoms of tetanus began in the neck and jaws. On April 8th there was tetanus, the pectoral and

abdominal muscles were characteristically rigid, and clonic spasms occurred about every ten or fifteen minutes. There was no difficulty in deglutition. Temperature 99°; skin sweating. He was ordered to be kept quiet in a darkened room; to take freely of light nourishment, and five grains of chloral hydrate with ten grains of bromide of potassium were to be taken every four hours. He got worse for a week, but took food freely. He then began to improve, and on May 11th was quite well. When the patient was convalescent, but the pectoral and abdominal muscles still rigid, the plantar reflex was tried, the leg muscles being flaccid, and was found normal. No other superficial reflex could be obtained. The patellar tendon-reflex, tried under the same conditions, was greatly exaggerated and ankle clonus was easily obtained. Tache cérébrale was readily produced. After the patient was well the patellar reflex was normal, and neither ankle clonus nor the tache cérébrale could be obtained.—Dr. Ransom had not been able to find any previous record of the condition of the reflexes in tetanus.—Mr. Shield related the case of a man admitted into Addenbrooke's Hospital with an extensive scalp wound, in whom symptoms of trismus supervened without spasm of any other muscles. He recovered after a month. He considered the favorable issue of Dr. Ransom's case most likely due to the fact that the man was able to swallow.

Editorial.

EXTREMES IN THERAPEUTICS.

If anything were wanted to quicken in medical men their intense desire to perfect their knowledge of Disease and its Remedies, it might be found in the fact that so much is being done in the press and in the daily newspapers to enlighten the public on this subject. Medical men have not only to discuss questions of disease and its treatment with each other, but with intelligent laymen who avail themselves of all means of gaining information on the fundamental principles of medicine. It is quite true that for years to come the intelligent laymen will not be able to make much of this study, and will be apt to arrive at conclusions not at first sight very complimentary to his intelligence. We are all humbled now and again to hear how this noble lord and that man of literature have adopted a belief in homœopathy or in a quack medicine, as the result of the attention which they have been able to give to medical subjects. But a little reflection on the complicated nature of medical problems and on the limitations of the best medical faculty will suffice to make practitioners very indulgent to those who reach crude or absurd conclusions.

In the current number of the *Quarterly Review* and the *British Quarterly Review*, respectively, there are two articles which are in point. The article in the *Quarterly* is "On the Progress of Medicine." It will repay perusal, from the sense of strict scientific justice and precision which the writer shows, and from his abstention from strong and extreme propositions. The article in the *British Quarterly*

is entitled "The Relation of Drugs to Medicine," and is signed "Baptist Crofts, B.A." Mr. Crofts' paper is also well worth reading. His main contention is that, both in medical practice and in popular habit, there is a marked tendency to abate the use of drugs; that, in fact, we are drifting, not slowly, to a system of drugless therapeutics, or to a time when therapeutics will be superseded by a perfect hygiene—when there will be nothing "to hurt nor to destroy." Mr. Crofts finds the chief explanation of this great change in the fact that medicine, in its studies and its objects, is becoming growingly more scientific, and especially more biological; that, indeed, medicine in its true sense has only lately come into existence, and is the child of biology. The writers of both the articles we have referred to see in disease only an awkward form of health, and in pathological processes only a modification or disturbance of physiological ones, with a marked tendency to right themselves and to revert to healthy conditions. There is nothing, as Mr. Crofts says, in this view really new. It was shared by Hippocrates and by Sydenham, and has always been most strongly held by sound medical minds. But it has grown stronger and stronger of late, and, according to Mr. Crofts, threatens the very use of drugs as factors in the removal of disease. Mr. Crofts himself admits that at present we are quite unable to dispense with the use of drugs. "It must," he says, "be at once admitted that for the immediate future certain drugs appear to be quite indispensable; that the offices they perform cannot otherwise be supplied. But," he goes on to say, "it is clear that a more scientific, because a more fundamental, principle of treatment is coming into play, in which drugs will take a very subordinate and adventitious part." Though there is considerable truth in this representation, we think the rôle of drugs is understated by Mr. Crofts, and that we are not within any measurable distance of the time in which physicians will be able to dispense with them.

It may be said with safety and literal truth that drugs never played a more important part than they do now, that they never did so much good and so little harm as in the present practice of medicine. Let one month be imagined in London without chloroform, opium, atropine, quinine, iron, salicin, and its compounds, carbolic acid, iodide of potassium, ammonia, without common laxatives or cod-liver oil, and suffering and death would be immensely increased. A few recent discoveries of the power of drugs over physiological and pathological processes are of the very highest scientific and practical interest: witness the influence of salicin over rheumatic pyrexia and pain, and of pilocarpine over the sweat and salivary glands. We can foresee no immediate millennium in which it would be possible to minister to disease and suffering without these helps.

We cannot close this article without directing

attention to the marked contrast between Mr. Croft's estimate of drugs and that which constitutes the basis of the system of Hahnemann, who has been, with wretched taste and judgment, called by his credulous disciples the Messiah of Medicine. The huge error of Hahnemann was in the supposition that nature played no part in the cure of disease, and that his petty medicines worked miracles. There was a moral element of vanity in this conception, as well as a scientific error of the first magnitude, which will for ever exclude him and his followers from the respect of scientific men. To teach that all disease is to be absolutely cured by medicine, and will for all time be incurable in any other way, and that for the cure of each disease there was one specific drug, with disease producing qualities, is a captivating doctrine for the ignorant and the credulous, but one which can have no place in the mind of scientific men. Hahnemann abandoned himself to his doctrine of specifics, and ridiculed that which Mr. Crofts and all sensible men see to be the fundamental rule in the treatment of disease—*tolle causam*. If we think that Mr. Crofts goes too far in under-estimating drugs, his error only shows more clearly the fundamental folly of that system in which they are all in all.

DISPLACEMENTS OF THE UTERUS AND DYSMENORRHOEA.

THE mechanical theory of uterine pathology, although the subject of very divergent opinions among gynecologists, has nevertheless met with a very large measure of acceptance at the hands of the profession. Whatever may be the reason for this—whether it be the generally acknowledged and indisputable fact that dysmenorrhœa and flexions are frequently met with together, or whether it be, as is maintained by its advocates, that a causal relation exists between the flexion and the suffering, or the charming simplicity of the theory itself—true it is that the evidence upon which the theory is based has been obtained from observations made in women suffering from uterine troubles, and from such only. It is therefore of a very one-sided character, and far from conclusive. During the last two years the theory has been the subject of a very critical examination; the evidence in its favor has been carefully sifted, while new inquiries based on scientific principles have been carried out, which throw a new light on so-called displacements, and which are calculated to settle finally the much-discussed question—the part played by flexions in the pathology of the uterus. These inquiries have been made to determine the position of the uterus (1) in women generally who sought advice for other than uterine troubles, (2) in those who did not, and (3) in those who did, suffer from dysmenorrhœa.

These researches have been conducted by Herman in London, and by Vedeler in Christiania.

We have on previous occasions directed attention to some of the results obtained by these observers. Additional observations by Vedeler are published in a late number of the *Archiv. für Gynecologie*. Herman examined 111 unmarried nulliparous women, who sought advice not for uterine troubles but for local contagious disease. In these he found the uterus anteфлекed in 67, or 60·3 per cent.; straight in 43, or 39 per cent.; and retroфлекed in 1. Vedeler examined 749 nulliparous women, and found the uterus anteфлекed in 66 per cent., straight in 31 per cent., and retroфлекed in 3 per cent. In virgins he found anteфлекion present in 71 per cent. In these calculations cases of uterine disease were not excluded, so that the great frequency of flexions of the uterus shown may be due to that circumstance. To obviate this source of error Vedeler examined 414 virgins and 506 nulliparous women in whom the uterus was healthy. In the former he found the organ in a state of anteфлекion in 296, or 71 per cent.; straight in 105, or 26 per cent.; and retroфлекed in 13, or 3 per cent. In the nulliparæ he found the uterus anteфлекed in 361, or 71 per cent.; straight in 128, or 25 per cent.; and retroфлекed in 17, or 3 per cent. So that, according to these observers, the prevailing position of the uterus is one of anteфлекion, and this prevalence extends to nearly three-fourths of all nulliparous women.

The second part of the inquiry had for its object the determination of the position of the uterus, not in women generally, but in women who suffered *no pain during menstruation*. Herman examined 42 nulliparous women who came under this division. In these, the uterus was anteфлекed in 26, or 62 per cent.; straight in 16, or 38 per cent. Vedeler examined 59 virgins and 101 nulliparous women who suffered no menstrual pain, and found the uterus anteфлекed in 68 per cent., straight in 30 per cent., and retroфлекed in 3 per cent.

The third object of the inquiry was to determine the frequency of so-called displacements in the subjects of dysmenorrhœa. Under this head, Herman gives the number of those who suffered slightly, as well as of those who suffered severely; while Vedeler gives the latter only. In 35 women who suffered slight pain during the period, Herman found the uterus straight in 15, or 43 per cent., and anteфлекed in 20, or 57 per cent.; in 35 who suffered severely he found the uterus straight in 12, or 34 per cent., and anteфлекed in 23, or 66 per cent. Vedeler examined 82 virgins and nulliparous women who suffered from severe dysmenorrhœa, and found anteфлекion present in 71 per cent, retroфлекion in 4 per cent., and the uterus straight in 24 per cent.

It will be noticed that there is a remarkable similarity in the results obtained by the two observers who apparently carried on their researches quite independently of each other, and probably about the same time. Herman finds throughout a larger proportion of straight and a smaller propor-

tion of anteфлекed uteri than Vedeler; but the difference is not great. They are agreed as to the enormous pervallence of anteфлекion of the uterus in the three classes of patients examined.

These figures show, further, that anteфлекion of the uterus is met with in about the same proportion in nulliparous women, from whatever class they are taken—whether from the ordinary run of women who seek advice for ailments other than uterine, or from those who suffer from dysmenorrhœa, or from those who menstruate without pain. In the three classes the proportions of straight and of bent uteri are almost precisely the same. According to Vedeler's statistics, the same is true of retroфлекion as of anteфлекion, except that the former is much rarer than the latter in nulliparæ; but the presence or absence of dysmenorrhœa seems to have no effect whatever on the percentage of retroфлекion any more than it has on the percentage of anteфлекion.

In addition to the preceding facts Herman found that of 57 women in whom the uterus was slightly or not at all flexed, 40, or 70 per cent., menstruated without pain, and 17, or 29 per cent., with severe pain; of 53 women with pronounced anteфлекion, 37, or 69 per cent., had no menstrual pain, while 13, or 30 per cent., had severe pain. He found, moreover, that of 23 cases of acute anteфлекion, 16, or 69·5 per cent., suffered no menstrual pain, while 7, or 30·4 per cent. only, had severe pain. In 87 others with slight anteфлекion there was little or no menstrual pain in 61, or 70 per cent., and there was severe pain in 26, or 29·8 per cent. These figures show that the same proportion of women suffer from dysmenorrhœa, be the uterus straight, slightly flexed, or acutely flexed. It appears, then, that from whatever point these observations are examined they lead to the same result—a result which entirely removes the ground from under the feet of the advocates of the mechanical theory of uterine pathology. These facts have been sought for, not in states of disease simply, but also in states of health, and unless the accuracy of the observations can be impugned and the error pointed out, the pathology based upon the mechanical theory must be discarded and replaced by another more consonant with the anatomy and physiology of the organs concerned.

BRAIN-WORK AND FOOD.

THE *Spectator* demurs to our doctrine that brain-work creates a demand for more and better food than ordinary muscular activity requires. "When THE LANCET insists on the necessity for a higher and better kind of food for brain-work than is needful for physical labor, it must mean a better food for persons liable to that extreme tension of the brain which really puts the mental powers on their mettle, and demands continuous and close attention of an anxious kind." No, that is not our meaning. We mean what we say: namely, that brain-work—which, by the way, is as much "phy-

sical" as any other description of work can be—is the function of a part of the organism which is specially eclectic in its relations to food. Brain and nerve tissue are of comparatively high organization, and the part they play in the economy of the organism is one of primary activity. They constitute the centres of its energy. They generate its force. They do not live simply for themselves, but for the whole body, and they require—to speak popularly—a specially nutritious form of food rich in nitrogen. In the article to which the *Spectator* takes exception, we were discussing particularly the case and condition of children, in which connection it was necessary to recognize an important fact which our contemporary seems to have overlooked—namely, that the brain is not only active but growing or *developing*. There is, in fact, as it were, a double claim upon the supplies: one to replace the daily use by exercise, the other to meet the demand of growth. We do not hypothecate any special "tension" as the cause of the need for higher and better food for brain-work. We say that an organism which is doing brain-work as well as muscular work requires higher and better food than an organism in which the brain is comparatively idle and only the lower centres and the muscles do much work. Undoubtedly the effect of brain-work is to strengthen the brain and to render it less likely to become abnormal in its structure or disorderly in its activity than if it were idle. Such exercise as the brain receives in education properly so called—that is, development of the faculties—stimulates nutrition, and in so doing increases the need for food. Excessive activity with anxiety, such as the *Spectator* contemplates, is not good at all, and ought to have no place in the educational process. Worry is fatal to good work, and to worry the growing brain of a child with work is to maim and cripple its organization, doing irreparable, because structural, mischief, the effects of which must be life-long. "Tension" in work is not a proof of strength, but of weakness. A well-developed and healthy-grown brain works without tension of any kind. The knit brow, straining eyes, and fixed attention of the scholar are not tokens of power, but of effort. The true athlete does not strain and pant when he puts forth his strength. The intellectual man with a strong mind does his brain-work easily. Tension is friction, and the moment the toil of a *growing* brain becomes laborious it should cease. We are, unfortunately, so accustomed to see brain-work done with effort that we have come to associate effort with work, and to regard "tension" as something tolerable, if not natural. As a matter of fact, no man should ever knit his brow as he thinks, or in any way evince effort as he works. The best brain-work is done easily, with a calm spirit, an equable temper, and in jaunty mood. All else is the toil of a weak or ill-developed brain straining to accomplish a task which is relatively too great for it.

FEMALE MEDICAL EDUCATION IN INDIA.

A most important step has just been taken by the Lieutenant-Governor of Bengal in connection with the education of females as medical practitioners in that Presidency. Last year Mr. Croft, Director of Public Instruction in Bengal, brought under the consideration of the Principal and Council of the Medical College in Calcutta the propriety of throwing open the medical classes to female students, with a view to their qualifying themselves for the license to practice medicine and surgery. The grounds upon which this recommendation was made were twofold: (1) Because a body of qualified practitioners would be thus formed where services would be available in the zenanas, where male practitioners cannot under any circumstances be admitted; and (2) it would open a career of usefulness to the native ladies who are now passing the University examinations. On that occasion, the Council, by a majority of four to one, passed resolutions unfavorable to the admission of ladies to the medical classes, and recommended the establishment of a separate college, if female medical education were deemed necessary. At the same time, they expressed an opinion that this was not requisite, but that an extension of the existing training in midwifery would be sufficient to meet the requirements of the case. Mr. Croft had also recommended that, if his suggestion were adopted, the qualification for entrance to the College should in the case of the ladies be lowered. The Council was unanimous in its opposition to this recommendation. The question was again brought forward this year by Mr. Croft, who forwarded to the Lieutenant-Governor the papers connected with his previous application to the Council of the College, supplemented by a letter from Dr. Coates, the Principal, reviewing the objections to the admission of ladies, and stating his opinion that there would be no difficulty in lecturing to mixed classes, and that no injurious consequences would result from their introduction. The Lieutenant-Governor, in a memorandum dated June 29th, has gone into a consideration of the whole question, and being of opinion that there is "an overwhelming weight of argument in favor of the admission of females to medical education, has overruled the decision of the Council of the College. He has at the same time negatived Mr. Croft's proposal to lower the educational standard of admission in favor of females, observing that "he knows of no profession in which a preliminary education, training the faculties of observation and thought, is more needed than in the profession of medicine. He therefore thinks that it would be conferring a fatal gift on the cause of female medical education to expose it to the risk of practical failure by withdrawing the necessity for that solid foundation of general knowledge on which the superstructure of technical information can alone be safely built."

He also throws upon Dr. Coates, as Principal of the College, the duty of making all the necessary arrangements as regards separate seats, screens, and waiting-rooms which may be necessary for the efficient and satisfactory working of the new system. The official documents, including Dr. Coates's letter, on which the Lieutenant-Governor formed his opinion, have not been published in the paper which has reached us, but even without these we have come to the conclusion that he has exercised a sound judgment in the decision which he has given. The condition of the native ladies when laboring under disease is most deplorable. Deprived, by the rules or prejudices of caste, of the services of medical men, they are left entirely in the hands of women wholly ignorant of the nature or treatment of disease, without any possible means of rescue from the consequences. Whatever may be thought as to the training of female doctors in our own country, there can be but one opinion, we think, as to its advisability, we may rather say the imperative necessity, for it under the conditions which regulate native female society in India. If judiciously carried out it cannot fail greatly to diminish unnecessary suffering and to save life. It will require sound judgment to be exercised, especially in the early stages, to prevent strong prejudices arising, which might counteract the anticipated benefits, but we have little doubt that every care will be taken on this head. We look forward with confidence to the gradual development of a system which will be productive of much substantial good in a direction which has hitherto been found to be impracticable.

CHOLERA PRECAUTIONS.

CHOLERA continues at Damietta, and isolated deaths have occurred at Port Said, Mansourah, and other Egyptian towns. The disease is also rumored to have come as near to us as the French port of Havre. Whether this turn out to be true or not, it is important that the sanitary authorities of our ports and their officers should know what steps to adopt in case of the arrival of any infected vessel within their jurisdiction. Quarantine, as such, we have happily discarded in this country, and we have no wish to return to a system which would compel a fleet of vessels with none but healthy people on board to lie off our shores for a number of days or weeks merely because they had come from certain ports, or which would require a ship containing a cholera patient to lie at anchor with its complement of passengers and crew until as many as were susceptible had contracted the disease, and this under conditions which would give the hitherto healthy the least possible chance of escape. Where the provisions of the Public Health and the Sanitary Acts against the spread of infection have been duly carried out, other infections have been effectually controlled, even when they have arisen in our midst, and

there is no reason why we should not be able to rely at least as fully on the same preventive measures in the case of an infection which can only come from without, and which before it reaches the community, has to run the gauntlet of what should be an efficient system of inspection in our ports.

An order issued by the Local Government Board on July 17th, 1873, lays down a code of regulations which should be adopted against the introduction of the disease into our country, and the duty of carrying them out devolves partly on the officer of Customs—a term including any person having authority from the Commissioners of Customs—and partly upon the Port Sanitary Authority and their officers. The Customs officer has the duty of ascertaining from the master of any vessel whether any person on board is suffering from cholera or choleraic diarrhoea, and if he has reason to suspect that any such disease exists, he has power then and there to detain the ship at anchor, and to refuse access to it to any person except an officer of the Port Authority, with whom he at once communicates, for a period of twelve hours. The port sanitary official, whether he has received his information through the Customs officer or not, may require any suspected vessel or any vessel which has come from a place infected with cholera, to be moored in some appropriate spot selected by the sanitary authority, and there the medical officer of health to the port, or some other qualified medical practitioner, has to examine all persons on board. If cholera or choleraic diarrhoea be discovered, the patients can at once be moved to any hospital provided by the authority, or if either no hospital be available, or the patients are not fit to be moved, the vessel must remain in charge of the port authority, and be subject to such directions as the port officer shall give. On the other hand, all persons found to be in health, and to have no suspicious symptoms, are, after medical examination, free to land immediately; the vessel, together with infected clothing, etc., remaining to be cleansed and disinfected after the last patient has been removed from it.

The above may be taken as a summary of the special action which is needed in view of cholera, and if the disease finds its way into our midst, notwithstanding the precautions specified, we may be certain that it would, as it has often done before, have equally evaded any system of quarantine. These measures are, however, only special ones. The ordinary everyday duty of sanitary authorities, both of our ports and of our inland districts, should be a preparation against infection, whether of cholera, or of any other specific disease, and even at this stage it is not too late to urge on all authorities the removal of all unwholesome conditions which are known to favor the spread of infection, and the provision of adequate means for the immediate isolation of any case of infectious disease which may be imported into, or appear in,

their districts. Were these measures universally adopted we could look cholera, and many other infections, calmly in the face, knowing that even if they ventured amongst us, they would soon expire from want of the needed pabulum on which to thrive.

THE ABSORPTION OF FAT IN THE SMALL INTESTINE.

It has long been a disputed question whether the fine particles of fat, which it is admitted on all hands are absorbed from the small intestine, enter the lacteals through the columnar cells which cover the villi or through minute channels left between these columnar cells; and various modes of preparation have been appealed to as affording the means of settling the question. Zawarykin, the well-known professor of physiology in St. Petersburg, has just advanced another view in the last part of Pflüger's *Archiv*, which he supports by strong evidence, to the effect that the lymph cells of the adenoid substance of the villi are the active agents in taking up the fat molecules from the intestine and transmitting them to the lacteals. In his experiments he has employed dogs, rabbits, and white rats, the plan adopted being to remove the intestines a few hours after a meal, and to treat them with osmic acid, and then to act upon them with picrocarmin, remove the water with alcohol, render transparent with clove oil, and finally mount in Canada balsam. In preparations thus made he states that lymph cells charged with fat may be seen in the layer of columnar epithelial cells, in the adenoid substance of the villi, and in other layers of the intestinal wall. Ordinary lymph cells thus treated exhibit nearly homogeneous protoplasm, which is of a greenish color; but those that are impregnated with fat present a mist of black molecules, which are not always evenly distributed through the mass, and cannot therefore be mistaken for the ordinary granulations of the protoplasm. The fat-containing lymph cells may be found in all zones of the columnar epithelium from the basal border to the subepithelial layer of endothelium, and they may even be seen to project beyond the basal striated border. The form of these cells varies considerably, suggesting that they are performing lively amoeboid movements when suddenly attacked and rendered immobile by the osmic acid. In some instances they present long processes, usually directed towards the basal border, and often containing fat molecules. The presence of such a long process, extending from a lymph cell lying near the attached extremity of the columnar cells to the basal border of the epithelium, and charged with fat molecules, would explain the views of those who consider that the fat molecules enter the intestinal wall between the columnar cells. Zawarykin is of opinion that his preparations tend to show that there is a constant movement in two directions of the lymph corpuscles, those that are desti-

tute of fat pressing towards the free surface of the mucous membrane and of the villi, whilst others charged with fat are moving in the opposite direction. The further transposition of the fat molecules is, he believes, in part into the central cavity of the villi, and in part along the adenoid tissue of the rest of the intestine. In both cases, however, they soon enter the plexiform chyle vessels, which are situated at the base of the follicles of Lieberkühn. A point of importance which he has noted is that the white corpuscles contained in the blood of the veins and arteries are also charged with fat molecules, but he is not prepared to state precisely how they obtain their fat. The follicles of Peyer's patches appear to be especially active in effecting the resorption of fat, as may be well seen in the case of rabbits. The fat may be seen in larger or smaller masses, composed of molecules and larger particles in the follicle itself, occupying both its peripheral and its more central part. The cells are particularly large in the portion of the intestinal coat which lies over a Peyer's patch, the leucocytes charged with fat here assume an almost colossal size, sometimes lying in rows parallel to the long diameter of the columnar cells, in others forming nests. The memoir is accompanied by some well-executed drawings by Rajewsky, which render the descriptions given by Zawarykin very intelligible.

REGINA v. TIMINS.

THE case of Regina v. Timins, which was tried at the recent Maidstone Assizes, presents many points of interest to the medical profession and the public. The facts, as summed up by Mr. Justice Day, may be stated as follows: Towards the end of last year the Rev. J. H. Timins, vicar of West Malling, sent to Mr. Steadman, the local chemist, for an ounce of oil of bitter almonds. Mr. Steadman prudently wrote to Mr. Timins, telling him that the oil was very poisonous and asking if it was the article he required. Mr. Timins replied by a letter produced in court which ran as follows (we copy the words from *The Times*):—"I require the bitter almond oil for external application, and I will see to its proper use." Thereupon Mr. Steadman supplied the oil in a bottle labelled "Essential oil of almonds—poison." Mr. Timins really used the oil as an outward application upon his son who was suffering from nettle-rash, and so far no harm was done. But, unfortunately, a few weeks later Mr. Timins called on a girl of about sixteen who was one of his poorer parishioners, and who seems to have been slightly indisposed. For some inscrutable reason the reverend gentleman poured into a wineglass a teaspoonful of the essential oil and persuaded the girl, against her wish, to drink it, saying that it would taste like wedding cake. The girl cried out once or twice and Mr. Timins gave her some water, but she died in an hour and three-quarters with

all the symptoms of prussic acid poisoning. It was stated that a medical man passed through the house while the girl lay dying, but that nothing was said to him of the occurrence.

Of course, an inquest was held, and a post-mortem examination, conducted by Mr. T. Henderson Pounds, of Snodland, and Mr. Herbert Pope, of West Malling, showed that there was nothing to indicate death from natural causes, but that the conditions pointed directly to death from prussic acid. The stomach, vomited matters, and other parts and fluids of the body were sent for analysis to Professor Heaton, of Charing-cross Hospital. Although a week elapsed before the analysis was commenced, prussic acid was found in the vomit and in the contents of the stomach, while the oil was detected in the blood, and its influence observed in the urine. In repetition experiments prussic acid was found in the contents of the stomach as long as fourteen days after death—an unprecedented circumstance, we believe. Mr. Timins promised to send the residue of the oil for analysis; but as he declared on a subsequent occasion that he had not preserved it, or even the label on its bottle, an analysis was afterwards made of the oil from which Mr. Timins was supplied by Mr. Steadman. It proved to contain 3·4 per cent. of prussic acid, so that a teaspoonful would contain almost exactly two grains of true acid, which, we need hardly remark, is a deadly dose.

The jury, to whom the above facts were very clearly stated by Mr. Justice Day, found the prisoner not guilty, after only a few minutes' consultation. We confess ourselves utterly astonished at the verdict. It is true that Mr. Timins not only had no intention of harming the girl, but had a very obvious intention of doing her good. But his own counsel, Mr. Edward Clarke and Mr. Douglas Kingsford, who defended the vicar with remarkable skill, admitted that as a matter of fact he killed her, and if the administration of prussic acid after such pointed warnings as Mr. Steadman's letter and the red poison label on the bottle was not an act of gross negligence, it is difficult to conceive what would be.

The moral of the history is that unqualified persons should never dabble with dangerous remedies or try to usurp the places of properly educated men. It is true that many—very many—years ago Mr. Timins acquired some smattering of medical science at St. Thomas's Hospital. But he never, as far as we know, passed a single examination, and his own evidence before the coroner showed how loose and inaccurate his medical knowledge was. We have made careful inquiries, and find that the poor of the West Malling neighborhood are generously and freely attended by the resident practitioners, and that Mr. Timins, whose irregular practice has long been a source of anxiety in his parish, has been led to it not by any necessity on the part of his flock, but by a restless vanity, which has at last led to the death

of an innocent girl. Let us hope that in future he will confine himself to the spiritual needs of his congregation.

One or two of the scientific facts elicited in this trial are worthy of notice. The crude essential oil, during rectification by sulphate of iron and me, loses on an average 9 per cent. of its weight, but the loss varies a good deal. Only a portion of this loss is hydrocyanic acid, and the percentage of hydrocyanic acid in the crude oil is sometimes much less than is commonly supposed. Professor Heaton found in one sample of crude oil recently prepared by a well-known firm (Messrs. Wright, Layman & Umney) only 2.5 per cent. of hydrocyanic acid. The crude oil, when carefully kept, does not seem to change rapidly. The sample from which Mr. Timins was supplied had been kept for at least eighteen months, and yet it exhibited little signs of alteration, and was hardly acid to test-paper. Of course it is impossible to say how much hydrocyanic acid it contained when new. The unusual length of time that passed before death, and the long preservation of the hydrocyanic acid in the contents of the stomach, have already been mentioned. Possibly both may be due to the same cause—namely, the retention and, so to speak, the preservation of the acid, by the essential oil. The two are, indeed, believed to exist in the crude oil in loose chemical combination. Nevertheless, it appears probable that the acid would not have been found at all but for the skill and care with which the post-mortem was made and the samples preserved for analysis.

THE PARKES MUSEUM.

An audience, which entirely filled the basement of the Central Hall, listened to the lecture delivered by Mr. Rogers Field. The three canons which regulate house drainage were given thus:—All refuse matter must be completely and rapidly removed. No passage of air can be allowed to take place from drains or waste-pipes into houses. No communication can be permitted to occur between the drains and the water-supply. The lecturer then proceeded to explain how the principles could be best put into practice. Drains to be self-cleansing must be laid in straight lines, must be watertight, and have a certain fall; the soundness of the pipes and joints can only be guaranteed when, the outlet being closed, the drain holds water without any leakage. Traps which allow of deposit, such as the D and dip varieties, must always be rejected. An excellent contrast was instituted between a form of the hopper closet, shown in action in the Parkes Museum, and the ordinary pan closet with its container, in which filth always accumulated. Waste preventers constructed on an ingenious application of the syphon principle were considered to be the best forms for flushing waterclosets. Well-arranged colored diagrams, with many models, served to illustrate the various details alluded to by Mr. Field. Two colored plans were hung before the audience to illustrate and give emphasis to the states of the drainage at 74 Margate-street, before and after the removal of the Parkes Museum there. It was shown how, in the present system, all the ter-

minals of the different drains had been brought to one central station, at which a manhole, very easy of access, was constructed. Dr. Alfred Carpenter, the chairman, spoke of the ridicule with which his suggestions on house drainage had been greeted not twenty years ago. After the usual vote of thanks, the lecturer proceeded to give demonstrations of the sanitary appliances in action in the various parts of the building.

The eighth lecture of the series was given by Dr. C. H. Ralfe on Thursday evening, July 12th, the subject being "Hygiene in Schools." The Very Rev. the Dean of Llandaff, Master of the Temple, took the chair. The lecturer, after dwelling on the importance of the subject, pointed out that great improvements had taken place of recent years in the general management of schools, but hand in hand with these improvements other conditions had arisen which had a tendency to lower the average standard of health at our chief centres of education. Among these the introduction of the competitive system must be reckoned as the chief, which, by introducing an element of strain, anxiety, and excitement at a period when growth and development were most active, proved highly prejudicial. There were other conditions, but these and the competitive system had to be accepted, and the evils resulting from them combated by an increased care and attention to hygienic details. The lecturer then proceeded to relate the best means for the protection of the school from the ill effects of defective drainage and a dangerous water-supply. The construction of the school buildings, and the arrangement of studies and dormitories, were fully considered, together with the question of ventilation and lighting. With regard to the latter, he drew attention to Mr. Brudenell Carter's remarks regarding the prevalence of short-sightedness and other ocular defects among schoolboys, remarks, the lecturer observed, which ought to be attentively considered by all parents and teachers. The channels by which epidemic disorders were introduced into a school, and the best means of dealing with an outbreak when it occurred, were next discussed. A considerable portion of the lecture was devoted to a consideration of the vexed question of school-boy food. The lecturer insisted it should be plain and simple in character, sufficient in quantity, excellent in quality, and adapted to the special requirements of growth and development according to the age of the boy, whilst the most minute attention should be paid to its cooking, and that it should be served hot and in a palatable and relishing form. He denounced the "sock" shops where boys are too often allowed to purchase provisions of a very doubtful nature, and consume them at times when they destroy the natural appetite. The influence of school work and play on the boy's health and development was then discussed. Sound honest hard work the lecturer was convinced never did a healthy boy any harm, but it was the system of forcing minds at high pressure which was accountable for many lamentable break-downs. For a similar reason athletic sports, which required previous training and often a severe strain, were not advisable till the frame was set, the ordinary pastimes of cricket and football being most suitable for the growing lad. In conclusion, the lecturer insisted on the necessity of adequate medical supervision in order to carry out effectually the details requisite for the maintenance of perfect sanitary and hygienic conditions, and alluded to the excellent results that had followed on the appointment of medical officers at Rugby and Marlborough to attend to these details, and who by constantly mixing with the boys obtained an intimate acquaintance with their physical condi-

tions, whilst the great advantage of medical supervision lay in the power of being beforehand with epidemics. In schools where it was thoroughly adopted the necessity for breaking up a school on account of scarlet fever, etc., was found to be of extremely rare occurrence.

Reviews and Notices of Books.

On the Treatment of Wounds and Fractures. Clinical Lectures. By SAMBSON GAMGEE, F.R.S.E., Consulting Surgeon to the Queen's Hospital, Birmingham, etc. etc. With 24 Engravings on Wood. Second Edition. London: J. & A. Churchill. 1883.

IN this single volume Mr. Gamgee has consolidated his two former well-known treatises on the treatment of wounds and on fractures. The lectures have been in great part rewritten, and the teaching shows considerable development in practical detail as the result of ten and five years' patient labor. Mr. Gamgee is an author who always well repays study; in addition to the stores of a large personal experience, he is able to draw from the published teachings of continental *confrères*, and still more happily from the classical writings of the fathers of surgery. The lesson implied by the title of this work, and effectively taught in its pages, that wounds and fractures are precisely similar in their nature, tendencies, and modes of healing, and that the principles of treatment for both are alike, is one that Mr. Gamgee has done good service in bringing forcibly before his readers. The terms in common use applied to the healing of wounds in soft parts are so different from those used in the union of fractures, that it is easy to overlook the essential oneness of the two processes, and yet the study of each throws great light on the other. Mr. Gamgee's chief aim has apparently been to bring out clearly what he conceives to be the *principles* of wound treatment, and while he shows by ample illustrations from his practice his own way of carrying out these principles, his readers are left at liberty to apply them any in way they think fit. These principles are immobilization, compression, dry and infrequent dressings; accessories being drainage, antiseptics, and position. It is impossible to read the facts related without being impressed with the value of the line of practice inculcated when carried out with discretion, skill, and confidence. The most striking part of Mr. Gamgee's book is that in which he explains the mode of action of properly applied compression, and illustrates its value by the recital of numerous cases in point. There can be no doubt that this is a powerful weapon in the surgeon's hand, which for the most part is far too little used. It is to be noted, also, that the dressing materials that Mr. Gamgee uses, his dextrinized millboard splints, and absorbent cotton tissue, are most excellent means by which compression and immobilization can be secured. We have not space to refer to the cases by which Mr. Gamgee illustrates his teaching; they are numerous, to the point, and well told. Among the most interesting are those in the chapter devoted to Head Injuries. But as they are all subsidiary to the great purpose in view of enforcing surgical principles, they must be read in their place to be appreciated. We may add that the volume closes with plain directions for the application of immovable splints of all kinds.

Nouveau Dictionnaire de Médecine et de Chirurgie Pratiques. Directeur de la Rédaction Dr. JACCOUD. Tome XXXIII. Pp. 828. 1882.

THE chief articles contained in this volume are Secretion, by Mathias Duval; Sensibility, by G. Ballet; Septicæmia, by A. Guérin; Simulées (Mala-dies) and Strangulation by Maurice Laugier; Sommeil, by M. Duval and Rey; Soufre, by A. Huton and Prunier; Sousclavière (Artère), by Poinso; Speculum, by Gallard; Sperme, by Duval and Vibert; Sterilité, by Siredey and Danlos; Stomatitis, by A. Chaffard; Strabisme, by Javal and Abadie; Strychnia and Strychnées, by Chapuis and Ovy.

M. Duval's article on Secretion is well worked up to the present day. After noticing the high temperature of the venous blood and of the secretion of the salivary glands, he observes that it is evident that phenomena of combustion are taking place in the cellules of the glands, due to oxygenation, or at least of disintegration, though of a complex nature. In proof of this he adduces the recent researches of A. Gautier on the alkaloids derived from proteids. Gautier and Selmi have, it is well known, discovered in putrefying corpses various poisonous alkaloids known under the name of *ptomaines*. Gautier has further shown that these alkaloids are normally found in most of the secretions, and especially in the saliva, a fact of great significance in relation to the nature of the acts of disassimilation, for the alkaloids in question are the products of anaërobic fermentation. This at first sight appears to be in contradiction with the fact of their occurrence in the healthy organism, for, according to classical notions, if the intimate acts of nutrition are comparable to fermentation, they can only be regarded as aërobic fermentations. On more carefully observing the phenomena, however, it does not necessarily follow that because oxygen is introduced to all parts of the body by the respiratory process and by the blood that the successive acts of assimilation and disassimilation must be aërobic. Indeed, it has been shown by A. Gautier that whilst four-fifths of our internal combustion are true aërobic fermentations, comparable to the oxidation of alcohol under the influence of the mycoderma aceti, one-fifth of the disassimilative combustion of the tissues in general and of the glands in particular is produced at the expense of the tissues themselves, and without the intervention of any extraneous oxygen. Hence it is reasonable to expect in these organs the same compounds that are found in putrid or anaërobic fermentations, such as ammonia, indol, phenol, and the butyric and acetic acids, as well as the organic alkaloids, often poisonous, which under the name of *ptomaines* have recently attracted so much attention amongst chemists. M. Duval discusses the question of the actual formation of the secreted matters, whether they proceed from cells which only yield up their contents or from cells which break down. In some instances, as in the case of the milk and in the sebaceous glands, all stages in the breaking down of the cell may be observed, whilst in the salivary glands the cells are persistent, and the changes they undergo have been well worked out by Heidenhain, Kühne, Lea, Langley, and others. From the researches of these observers it is seen that there are two types of glands. In one, the albuminous type of gland, represented by the parotid of the rabbit, during repose the cells swell, and contain a large quantity of clear material, to which the term "*paraplasm*" has been given, which does not color with carmine. After action the cells become smaller, the paraplasm in great part disappears, and a granular protoplasm re-

mains which does color with carmine. In the mucous glands, represented by the submaxillary and sublingual, there are two kinds of cellular elements—voluminous, transparent cells of cylindrical or pyramidal form, with the base applied to the wall of the acinus, and a flat nucleus; and smaller, angular cells, formed of granular protoplasm, with rounded nucleus. Three or four of these compressed together form the demilunes of Gianuzzi. In action the larger cells disappear, and a new epithelium lines the cul-de-sac. The action of the nervous system on secretion is by no means briefly given, though the subject is dealt with under the heads of the several secretions. He regards the statements of Pflüger in respect to the termination of the nerves in the cells as still doubtful.

Under the head of Speculum drawings of a great variety of specula are given, several of which, if a paragraph in one of the daily papers be true, were in use in Pompeii two thousand years ago. A very useless woodcut is given, intended to show the mode in which the speculum should be introduced. The patient is here shown lying on the back. The speculum can be introduced just as readily, and much more decently, with the patient lying on one side. A drawing is also given showing how a silver spoon may be attached to a wax candle, and made to serve very well instead of a reflector.

The article Sphygmograph, written by Brouardel, who has devoted much attention to it, and made it the subject of his thesis when taking his degree, gives a full account of the method of employing the instrument, and many tracings or, as he terms them, sphygmograms.

Under the head of "Sommell" not only are the physiological characters and conditions of sleep given, with the views of Durham, Hammond, and Sanson on the causes of sleep, but an interesting section is appended upon lethargy, sleeping sickness, or Nelavan, the disease first clearly defined by Winterbottom in 1819, and observed by him in the slaves of the Bay of Benin. Of late years it has been noticed by many authors, but it is curious that it should have been so long undescribed. It is a malady chiefly affecting the inhabitants of the Western Coast of Africa, but has also been seen at Martinique and at Guadeloupe. The affection is preceded by general lassitude, by irregular appetite, and by irregularity of pulse. The patient becomes unable to raise his lids, and sleep seizes on the whole man. Strong stimuli are required to awaken him; hunger and thirst are unnoticed; and after a sleep of two or three days consecutively sleep deepens into death, the change occurring so gradually as to render it impossible to fix the moment of dissolution. The general physique of the body is well maintained. After death, the chief pathological change observed is congestion of the meninges. The cephalo-rachidian fluid is often increased in quantity. No treatment seems to be of service.

Selections from the Works of the late J. Warburton Begbie, M.D., LL.D., F.R.C.P. Edin., Physician to, and Lecturer on Clinical Medicine in, the Edinburgh Royal Infirmary, and Lecturer on the Practice of Physic in the Extra-Academical School. Edited by DYCE DUCKWORTH, M.D. Edin., F.R.C.P., Assistant-Physician of St. Bartholomew's Hospital, etc. The New Sydenham Society.

THE New Sydenham Society has acted well within its best purposes in publishing this selection from the works of the late Dr. J. Warburton Begbie, who

died so sadly too soon both for Scotland and for the practice of medicine. The selection of Dr. Duckworth as editor, on his own kind offer to undertake the work, is equally happy with the main publication. Few men could have been found to whom the labor would be more—to use his own words—a labor of love. Dr. Duckworth, above all things, looks up lovingly and reverently to his *alma mater*. He looks back fondly to the time when he took from her his first great lessons in medicine; and of the men typical of that time he can find none more worthy of study and attention, and we may add, affection, than the younger Begbie. And no one with similar means of judgment will differ from Dr. Duckworth in his estimate of Begbie. He was indeed "the beloved physician," and lives, not only in the gratitude of the patients whom he advised, but in the respect of the profession which he adorned. The papers gathered together by Dr. Duckworth are not only permanently valuable in themselves, but give an excellent idea of the qualities, human and professional, which raised Begbie to the foremost place among the physicians of Scotland. They are models of clinical work, and full of fine touches of feeling and of careful observation. We commend them heartily to the profession for study and for imitation. Dr. Duckworth specifies a few of the most valuable:—1. On Temporary Albuminuria, occurring in the Course of Febrile or other Acute Diseases. 3. On the Use of Belladonna in Scarlatina. 9. Case of Fatal Croup in the Adult. 12. On Lead Impregnation, and its connection with Gout and Rheumatism. 16. Vascular Bronchocele, and Exophthalmos. 19. On Paracentesis Thoracis in the Treatment of Pleural Effusions. 24. The Therapeutic Action of Muriate of Lime. 25. The Swelled Leg of Fevers. 28. Albuminuria in cases of Vascular Bronchocele and Exophthalmos. But there are others equally good, amongst which we would specify a paper on Cases of Cholera, and one on Hæmaturia. All alike give the idea that the writer was not a mere pathologist, but a physician trying to abate suffering and control disease. The papers are preceded by a memoir of Begbie by Dr. Duckworth, which will be read with great interest.

Abdominal Hernia and its Consequences, with the Principles of its Practical Treatment. By RUSHTON PARKER, B.S., F.R.C.S., Professor of Surgery in University College, Liverpool. Liverpool: Adam Holden. 1883.

THE first part of this essay consists chiefly of a plea for more careful treatment of cases of functional laming of the alimentary canal. Mr. Parker points out that in all cases of intestinal obstruction there is more or less of this functional disturbance of the digestive organs, and that the only proper treatment for it consists in rest, which is to be obtained by entire abstinence from food, and all physical exploration of the parts, enemata, etc., and the exhibition of opium or morphia. This is an important truth, and one that is easily overlooked, and Mr. Parker has done well in calling attention to it. But in his desire to enforce his views, we fear that the writer has in several instances considerably overstated his case. In the first place, he has nowhere drawn any distinction between the symptoms and effects of mere obstruction to the passage of feces and of superadded strangulation of the vessels and nerves of the part, and yet this distinction lies at the very root of the symptoms, pathological processes, and results. To plead as he does for a "generalization of the symptoms in all kinds and every degree of intestinal obstruction, mechanical and functional," is to

plead for a truth so partial as to verge upon error. When we read that it is not only useless but injurious to give food "in any form of intestinal obstruction," it is evident that the author is thinking of strangulation or of certain forms only of obstruction, and has made a far too hurried generalization, for we cannot suppose him to mean that we should refuse all food to patients with, say, cancer of the rectum.

Two other points are touched upon by Mr. Parker in this part of his essay. One of these is the alleged production of intestinal obstruction by nipping off omentum in a hernial sac, in the face of the fact that tight ligature of omentum is known not to produce any such symptoms. Mr. Holmes is criticised for believing in this paradox, although unable to explain it. But surely the facts that Mr. Holmes and others adduce are very stubborn things, and are not to be set aside by a theoretical objection which on examination is seen to be unsound; for there is a vast difference between cutting off a piece of omentum and putting a tight ligature on the pedicle, and strangulation of omentum, with its attendant venous congestion and nerve irritation.

The other point referred to is the difference between intra-peritoneal and extra-peritoneal perforation of intestine. It is insisted that the mere perforation of intestine is not directly important, and may be harmless, or at least not fatal. The gravity of intra-peritoneal perforation is attributed entirely to absorption of septic matters from the extravasated fæces, while the effect of fecal examination in producing shock is entirely overlooked, although in a large proportion of the cases the evidence of this peritoneal shock is not wanting.

The second part of the essay is devoted to a consideration of the radical cure of hernia. It is rightly urged that no operation for strangulated hernia should be considered complete in which precautions are not taken to ensure a radical cure. The method advocated by Mr. Parker is the "ligature of the peritoneal lining, with or without other coverings, at the offset of the former from the main peritoneal pouch, by means of anti-septic catgut," or other similar material. This is described as the only method applicable to all herniæ alike. We cannot but regret that in this particular, again, Mr. Parker has overstated his case, and, indeed, we have only to read his own statements in this very paper to find a contradiction to this thesis. We read that where the hernial aperture is small, the above procedure succeeds, where large "it most easily fails;" and, again, Mr. Parker admits that in one of his cases he had "to sew up the pillars of the ring, in order to keep the hernia reduced." The truth appears to be that for radical cure of hernia two things are needed—the closure of the neck of the hernial sac and the restoration (where impaired) of the normal support from fibrous tissues at the implicated region. We believe that Mr. Parker is, in fact, fully alive to this, but in his enthusiasm for simple closure of the sac he has been betrayed into the use of too strong and too general language.

SPAS AND MINERAL WATERS.

The Mineral Waters of Europe, including a short Description of Artificial Mineral Waters. By C. R. C. TICHBORNE, LL.D., F.C.S., Professor of Chemistry at the Carmichael College, Dublin, and PROSSER JAMES, M.D., Lecturer on Materia Medica and Therapeutics at the London Hospital. London: Baillière, Tindall & Cox. 1883.—The treatment of various diseases by baths and mineral waters is

daily attracting more and more attention. There is, of course, nothing peculiar or special in this mode of administering drugs, for mineral waters are simply medicines of complex composition, largely diluted, and containing in solution various salts and gases derived from the soils through which they pass. The book before us is replete with valuable information, and contains much to excite the interest and curiosity of those who have not made the subject a special study. We are told in the preface that nearly all the waters in general use as medicinal agents have been submitted to careful chemical analysis, the work extending over a period of nearly three years. It cannot be too generally known that the analyses of waters as given in many of our text-books are anything but reliable. They have been copied and recopied year after year, and not only has every error been perpetuated with religious fidelity, but in many cases they were originally obtained from advertisements issued by the proprietors or others interested in the springs. It should be remembered, too, that mineral waters are liable to change from time to time in chemical composition, this variation being most marked in those containing large quantities of salts in solution. During the last few years the whole subject of water analysis has undergone a complete revolution, the spectroscope now affording means of detecting small quantities of the rarer metals not possessed by chemists fifteen years ago. Professor Tichborne, for example, in 1868 found lithia for the first time in the Schwalheim waters, although they had been carefully examined by Liebig only six years previously. Another point of practical importance is that many so-called mineral waters have in reality no claim to that title, their constituents, especially in the case of sulphuretted waters, being merely the result of decomposition attending the decay of organic matter. In several instances it was found that waters supposed to possess valuable medicinal properties were little more than a mixture of sewage and water. The authors find that in most cases artificial substitutes are not at all equal to the waters they are supposed to represent, and they assert that the more complex spas can never be imitated. It must not be forgotten, in considering the composition of mineral waters, that as regards the arrangement of the elements by the chemist there is a good deal of theory. He evaporates down a certain bulk of water, estimates the relative amounts of acids and bases present, and then arranges them in his report according to their known affinities, but so many changes have taken place during the process that the arrangement which he is authorized in mapping out does not of necessity represent the true arrangement existing in the waters themselves. The authors have arranged the different mineral waters in groups according to their action: thus we have a group of purgative waters, of alkaline waters, of arsenical waters, of chalybeate waters, and so on. Each group affords material for two chapters—one devoted to a consideration of its chemical characters and the other to its medicinal uses. The book contains the results of much good sound work, and the authors are to be congratulated on the success of their efforts to treat the subject in a truly scientific spirit.

The Thermal Springs of Aix-la-Chapelle and Borette. By Dr. BEISSER. Aix-la-Chapelle: J. A. Mayer. 1883.—Aix-la-Chapelle, as is well known, is now largely resorted to by sufferers from syphilis. The treatment of this complaint has become quite a speciality both at Aix and Borette (Burtscheid), the number of visitors seeking relief steadily increasing year by year. The method employed is

to rub in mercury in the form of ointment, the skin having been previously prepared for its absorption by the use of hot sulphur baths and by drinking the waters. Much apparently depends on the mode in which the inunction is performed, the rubbers at Aix being trained for the work by physicians who devote special attention to the subject. But it is not only in syphilis that the hot sulphurous waters of Aix are beneficial, for it is asserted that they prove curative in almost all forms of gout and rheumatism. In many skin diseases, especially chronic cases, the baths may be used with advantage. Dr. Beissel warns us that in acute eczema they must be avoided, for they do more harm than good. For chronic localized eczema he recommends a mode of treatment which yields excellent results in his hands. The crusts are thoroughly soaked in oil at bedtime and removed the next morning in the bath. No crust of any kind is allowed to remain on, they must be removed entirely, even at the risk of exciting bleeding. The reddened and freely discharging surface is then carefully dried and painted with a one-in-ten solution of permanganate of potash. The painting is to be repeated once or twice a day, and is to be persevered with until a black scale of the thickness of a sheet of paper forms over the eczematous spot. After this mode of treatment has been continued for a week, the dried black mass is allowed to separate and the cure is almost complete, although in places there may still be little fissures or cracks. Dr. Beissel's descriptive history of the towns of Aix and Borectte is amusing.

Medical Guide to the Mineral Waters of France and its Wintering Stations. By A. VINTRAS, M.D., Physician to the French Embassy, Senior Physician to the French Hospital in London, Chevalier de la Légion d'Honneur. London: J. & A. Churchill. 1883.—The object of this work, we are told, is to afford the means of ascertaining at a glance the chemical composition, therapeutical value, and geographical situation of the most important thermal stations in France. Dr. Vintras has consulted the latest monographs and other writings on the subject, in order to bring the information up to date, but his work is not a mere compilation, for he has personally visited all the most important springs of which he treats. He writes clearly and pleasantly, and his descriptions of Vichy, Royat, Mont-Doré, La Bourboule, and other places of resort, should add largely to the influx of English visitors. His chapter of advice to invalids who think of taking the waters is excellent. The first point on which he insists is that the patient should never go to any mineral water station without first consulting a physician. "Whatever friends or acquaintances may say, however much they may have been benefited by taking the waters at such or such a place, turn a deaf ear to their well-intentioned but very dangerous advice. Mineral waters are just as much a remedy as any medicine compounded by chemists, and their properties are as different as those of various prescriptions, although their composition appears to be the same or nearly so. It is the nearly so which makes the great difference to be fully realized only by those who have made a special study of this important matter." On arriving at the springs, the first thing to be done is to call upon the physician to whom an introduction has been obtained at home, in order that his advice may be taken as to the mode of treatment to be adopted. Patients should be guided in everything by their medical adviser, and should not listen to suggestions made by persons met casually at the hotel or elsewhere. The usual stay at

a mineral station is three weeks—that is, twenty-one days of actual treatment; but when this is over it is not advisable to hurry back too quickly, for the medicinal effects of the waters continue for some time longer, and if possible a week's rest should be taken at one or more places of interest on the road home. In an appendix the author gives some account of the legislative enactments relating to mineral springs in France. It appears that no spring can be worked medically or commercially without a special authorization from the Ministers of Commerce and Public Works, and this is granted only after a favorable opinion has been pronounced by the Academy of Medicine. A medical inspector is appointed to every locality possessing one or more establishments of natural mineral waters, and during the season this official exercises a supervision over everything appropriated to the treatment of patients. In the appendix will also be found a series of itineraries from Paris to the principal French thermal stations, the information being clearly and concisely arranged. There are, we must admit, one or two things in this volume which have puzzled us. For example, speaking of Royat, the author says:—"The discovery that lithine (chloride of lithium) existed in considerable quantities in the Royat water has for the last few years attracted to this station a large number of gouty patients," and yet on turning to the accompanying chemical analysis, said to be the "latest that we possess," we find no mention of the presence of lithia in any of the springs. When the particular analysis was made we are not told, but it certainly differs very materially from that made by Willm in 1879, and also from that quoted in the "*Notice sur les Eaux Minérales de Royat.*" Dr. Vintras is perhaps more at home as a descriptive writer than when dealing with scientific facts.

Medical Guide to Contrexéville (Vosges). By Dr. DEBOUT D'ESTRÉES, Chevalier de la Légion d'Honneur. London: J. & A. Churchill. 1883.—The mineral waters of Contrexéville have long enjoyed a reputation for the cure of stone, and they are often spoken of as "the antidote to gravel." They were found by Civiale to be specially useful in restoring contractility to the bladder weakened by chronic catarrh. In gout and its allies they prove almost as successful as in stone. Dr. Debout d'Estrées gives us in a small compass all we are likely to want to know about his favorite watering-place. He tells us how to get there, what to do when we are there, and even lays down rules for our guidance when we have ceased to be under his care. His chapter of "General Information" is interesting, and certainly practical. He reminds us that there are certain formalities to be complied with before we can be permitted to drink the waters: the first being to go to the office and pay the sum of twenty francs. He gives the prices of the baths, which certainly seem to us to be higher than at most continental watering-places. The work on the whole is well done, and will repay perusal.

Vichy and its Therapeutical Resources. By PROSSER JAMES, M.D., Lecturer on Materia Medica at the London Hospital. Fifth Edition. London: Bailière, Tindall & Cox; Alexander & Shepherd. 1883. Vichy is said to be visited annually by 40,000 invalids and tourists, so that it is hardly a matter for surprise that Dr. Prosser James's interesting little book should have run through five editions. It is readable, and contains a great deal of useful information. The present edition has been corrected up to date, the author having recently visited Vichy for the purpose.

Meade's Manual for Students. Fifth Edition, entirely rewritten. By JAMES CANTLIE, M.A., M.B., F.R.C.S., Assistant-Surgeon and Demonstrator of Anatomy, Charing-cross Hospital; and DANIEL COLQUHOUN, M.D. Lond., M.R.C.P., Assistant-Physician and Lecturer on Botany, Charing-cross Hospital. London: Renshaw. 1883.—We had thought, and certainly the wish was father to the thought, that manuals containing everything that is supposed to be required for medical examination had disappeared before the advances and alterations in the method of examination which all qualifying bodies have been making in the past few years. A single examiner, asking questions on botany, chemistry, anatomy, forensic medicine, materia medica, medicine, and midwifery is now a thing of the past; and works, originally intended to meet this condition, can hardly survive, even if revised and rewritten, and we need not deplore their extinction, nor the examination system which called them into existence. We would remark that the new editors of this manual are scarcely justified in basing their defence of cram on the statement that the duration of the course of medical study is now practically limited to two and a half years, for few students pass under four years, and for every one who is qualified within this period, ten may be found studying beyond it. In conclusion, we must add that if books of this class are to be used, this manual is one of the best, and the information contained in it is quite up to date.

The Student's Handbook of Surgical Anatomy. By JOHN McLACHLAN. Edinburgh: E. & S. Livingstone. 1883.—This is a very valuable little book for advanced students who are preparing for an examination in surgical anatomy. It is very correct and well arranged, but unfortunately it is incomplete. A new edition should at least contain, in addition, an account of the surface markings and a description of the arrangement of the fasciæ.

Study and Stimulants. Edited by A. ARTHUR READE. London: Simpkin, Marshall & Co. 1883.—This book is something of a new departure in its method of dealing with the questions of the value of smoking and the use of stimulants. An alternative title appears on the front page: the use of intoxicants and narcotics in relation to intellectual life as illustrated by personal communications on the subject, from men of letters and of science. In a work thus composed, elements of curiosity and of interest are introduced quite apart from the problem immediately in hand. There is certainly a little enjoyment to be derived from reading what this great man says or that learned writer thinks. Our own views on these matters have been so freely and so recently expressed that we are loth to return with any degree of fulness to the matter. The conclusions at which the author arrives are laid down by him in a table of seven propositions. The first statement avows that alcohol and tobacco are of no value to a healthy student. That is undeniably a safe proposition to lay down, the adjective "healthy" will cover a multitude of objections. That the most vigorous thinkers and hardest workers abstain from both stimulants is a deduction which is not perfectly free from fallacy. We can hardly agree with the opinion that almost every brain-worker would be the better for abstinence, though we can easily understand how the most abstruse calculations may be made, and the most laborious mental work performed without artificial stimulus. It may be worth while to consider what is the real difference between the natural and the artificial. Surely that might once have been regarded as artificial

may come to be looked upon as natural. Use is second nature. But we feel strongly inclined to ask, What is first nature? Was it not truly an artificial experiment when the first beginnings of organic life began? The author gets into deep water when he believes that all work done under the influence of alcohol is unhealthy work. That is a very bold assertion to make and the onus of proving the statement rests with its asserter. Unless we have taken altogether a wrong view of pharmacology and therapeutics, we think that there are certainly many more brain stimulants than the author's external ones—fresh air, cold water, walking, riding, and other out-door exercises. With what object the adjective *pure* (brain stimulant) is introduced does not at first sight appear. If it be meant that the stimulant acts solely on the brain we cannot consent, and if he regard the stimulants mentioned as the only pure ones we are yet not satisfied. Or perhaps what Mr. Reade calls a stimulant we should consider as essential to vital existence, and of so mild a nature that the term stimulant might with advantage be dropped. We think most people will agree with us that to speak of fresh air and cold water as stimulants is an abuse of the terms.

Descriptive Catalogue of the Pathological Specimens contained in the Museum of the Royal College of Surgeons of England. Second Edition. By Sir JAMES PAGET, Bart., with the assistance of JAMES F. GOODHART, M.D., and ALBAN H. G. DORAN, F.R.C.S. Vol. II. London: J. & A. Churchill. 1883.—This volume contains a description of more than 1500 specimens, including all those in the museum illustrating morbid conditions of the blood, injuries and diseases of voluntary muscles, tendons and their sheaths, cartilage, bone, joints, and of the vertebral column; diseases of bursæ and synovial ganglia, and distortion of the pelvis. The Catalogue testifies to the great wealth of the museum, especially in specimens of disease and injury of bones. The descriptions of the specimens are very exact and lucid, and form an invaluable guide to all students visiting the museum. The preparation of such a catalogue entails immense labor upon its authors, and it is difficult to estimate the value of the services Sir James Paget and his two assistants are rendering to the profession by this undertaking. Their best reward would be to find that the new catalogue acts as a stimulus to all who have it in their power to avail themselves of the vast stores of information collected in the Hunterian Museum.

The Quarterly Journal of Microscopical Science. Edited by E. RAY LANKESTER, THISELTON DYER, E. KLEIN, H. N. MOSELEY, and ADAM SEDGWICK. New Series. No. XCI. July, 1883. London: J. & A. Churchill.—The memoirs in this number are:—1. On the Ancestral Form of the Chordata, by A. Hübner, in which the learned professor of Utrecht, whilst admitting the validity of Ray Lankester's view, that the Tunicates are rather to be regarded as degenerate vertebrates than as representing the dawn of the vertebrate series, advances a very curious doctrine, to the effect that "the proboscidean sheath of the Nemertean is comparable in situation (and development?) with the chorda dorsalis of the vertebrate." This view is advocated with much acumen, and supported by many arguments. 2. The Renal Organs (Nephridia) of Patella, by J. T. Cunningham. 3. A Rare Form of the Blastoderm of the Chick, and its bearing on the question of the Formation of the Vertebrate Embryo, by C. O. Whitman, Ph.D. 4. On the Development of the Pelvic Girdle and Skeleton of the Hind Limb in the Chick, by Alice Johnson, Newnham College, Cambridge. 5. The Development of the Mole

(*Talpa Europæa*); the Formation of the Germinal Layers and Early Development of the Medullary Groove and Notochord, by Walter Heape. 6. The Tongue of *Ornithorhynchus paradoxus*; the Origin of Taste-bulbs, and the parts upon which they occur, by Edward B. Poulton. 7. Observations upon the Foetal Membranes of the Opossum and other Marsupials, by Henry F. Osborn. There are eleven plates in this number.

Medical Annotations.

"Ne quid nimis."

WINDOW VENTILATION.

No time could be better than the present for beginning the practice of house ventilation by the window, which is still, in the majority of houses, the readiest and the safest means of obtaining a regular and constant supply of fresh air. This practice, begun in warm weather, may be carried on with proper care through autumn and winter. The constantly accumulating impurities derived from breath, from perspiration, from excreta of other kinds collected in sleeping-rooms, from the use of gas or lamplight, and too often, even now, from suction of sewage-gas from waste-pipes by the heat of house fires, etc., render it as necessary for health as for comfort that these should have free egress, and that they should be substituted by the pure outer air. Fresh air from without may very easily be had without draught, and without risk of cold even to delicate persons, if a few simple rules be observed. The cold air of winter of course enters with greater force, and in greater proportional volume than the more equable summer air, into a warm room. The aperture of ingress must be correspondingly diminished. Air from a window is preferable to that from an opened inner door, no matter how roomy the house, from its more reliable purity. If the window be the inlet, the fire, fireplace, or it may be the door of a room in summer acting as an outlet, it may be opened from the top, the extent being regulated according to the outer temperature. There is then a direct inward current at the upper part, which follows the roof of the room, thus mingling with any heated waste products which require to be removed, and an interrupted current at the middle, the previous line of junction of the upper and lower sashes; both are broken and diffused by the blinds or curtains. Venetians for this purpose should be turned upwards. A window should never be made to ventilate by opening it from below, unless the open lower space be filled up in some way, and ventilation be carried on at the middle, where the sashes join; otherwise draughts are unavoidable. The ventilating-pane is a hardly less simple and equally efficient and safe method with either of the others. Window ventilation is especially useful in bedrooms, and its efficiency or otherwise cannot fail to affect the vital powers of the occupant, who in his slumbers must trust to other energies than his own for the removal of those impurities and morbid germs which his every breath multiplies around him.

ALLEGED INCREASE OF INSANITY IN THE UNITED STATES.

We must confess our inability to understand how it comes to pass that the professors of statistical science, in reference particularly to what are known as "vital statistics," do not yet perceive the fallacy of "increments" of integral classes of the

population, calculated on the bases of successive censuses. Even if there be a given number for the whole population at one period of census-taking, and another number—say ten per cent. greater—when the next census is taken, it does not necessarily follow that the population has increased ten per cent. in the interval, as compared with the increase in any previous interval of like duration. It may very well happen that some devastating war or epidemic may have prevented the survival of a certain percentage of those who were alive at the commencement of the earlier interval until the close of it, so that the difference between the numbers polled at the beginning and at the end of the earlier interval may not have been so great as it would otherwise have been, and not so great comparatively as the difference between the census taken at the commencement and the census taken at the conclusion of the latter interval. It seems to be forgotten that mere difference between returns at successive periods throws no statistical light whatever on what has happened in the interval. Comparisons of birth-rate and death-rate are needed to interpret the import of successive census returns, and without such comparisons these returns are not simply worthless, but may be actually misleading. Now, when we come to compare the returns made to the Commissioners in Lunacy at the commencement of each year, we are comparing successive censuses, and no sort of conclusion can be drawn without taking steps to ascertain how any increase which may have occurred is to be explained. Has the number of admissions been greater during this year than formerly? If so, to what extent has this been due to the fact that, more accommodation having been provided, it has been occupied? Again, has there been any proportional decrease in the death-rate? because, if so, obviously a number of individuals who, according to precedent, would have disappeared from the roll during the year have not disappeared, and now help to swell the total? Further, have any changes in policy or administration, such as a broader interpretation of the meaning of "insanity," naturally leading to the extension of the class thus designated, or greater vigilance on the part of those charged with the duty of searching out and classifying the "insane," occurred? Clearly, these and other factors of the result must be examined and estimated before any trust can be placed in the returns made. Meanwhile these returns are mischief-making; they keep up a vicious circle of activity, producing an increase of asylum accommodation which we believe to be perfectly unnecessary, and which must inevitably lead to an apparent increase in the number of the "insane." When, therefore, we hear of a "startling increase" of insanity in the United States, we simply decline to believe in it. General indications of the state of mental health in America do not bear out the inference to which statistics point; and, as "vital statistics" are at present computed in this country and in America, we are convinced that general indications are more trustworthy than figures which may not be facts.

BOVINE OR HUMANIZED LYMPH.

We have received a communication from Dr. Thomas F. Wood, Secretary to the North Carolina Board of Health, in which he adverts to an article which was recently published in *THE LANCET*, and which referred to the observations made by several American physicians as to certain advantages attendant upon the system of arm-to-arm vaccination. Dr. Wood is of opinion that the quotation which we made from a report of his does not correctly express his views upon the

question as to whether the use of bovine lymph should or should not supersede the use of humanized lymph. Regarded from this point of view we admit Dr. Wood's contention, and we have pleasure in giving prominence to the opinion he has expressed on the subject. Dr. Wood's view is that although there are certain advantages connected with the arm-to-arm system as carried out in this country, "where vaccinations are done faithfully and show excellent results," yet that the advantages attendant upon the use of bovine lymph are still greater, and this mainly on the following grounds:—1. Bovine lymph gives all the results of original vaccinations as described by Jenner and others. 2. This lymph has in his practice appeared to be superior in potency to humanized lymph in cases of revaccination. 3. The tendency of the course of humanized lymph is, after a long series of years, towards degeneration, in so far as its protective power is concerned. 4. Humanized lymph has been known to act as a medium for the transmission of diseases affecting the human subject, whereas no such results are as yet known to have followed on the use of lymph direct from the calf.

THE ABOLITION OF HOSPITAL CHAPLAINS IN PARIS.

WHATEVER the antagonism of the present rulers of France to the national religion of that country, the abolition of the hospital chaplains must be regarded as a most extreme and cruel measure. It is not a question of creeds. It is the deeper question of religion, and of provision for the consolation of sick or dying persons. Violently to withdraw such a provision from the thousands who fill the hospitals of Paris is an outrage on the religious sentiment of the people immediately affected, and of the nation itself. We shall not be suspected of any undue respect for Catholic priests, or their ministrations; but we know what are the susceptibilities and the wants of the sick and of the dying—whether Catholic or Protestant. We know how resolutions for a better life, or considerations favorable to a happier death, may be fostered. In Paris, where the hospital system is so highly organized, the withdrawal of such a provision is more than usually offensive to all good taste and feeling; and we venture to believe that it will be reconsidered. The hospital is not the place to fight the battle of reason *versus* faith, and those who force such a fight in such a field will have the worst of it.

HYPODERMIC INFLATION.

DR. HENRY R. SILVESTER, who has already rendered such valuable services in connection with the restoration of persons apparently drowned, has been recently making some observations with a view to the prevention rather than the treatment of this condition. It is stated that he was led to this investigation from being brought into contact with the many life saving apparatus at the Fisheries Exhibition, in his capacity as chairman of jury, Group 7. His method is the artificial production of subcutaneous emphysema. He showed at the Exhibition a small dog, weighing 10 lb., whose subcutaneous tissue he had inflated with air, and which was then able to sustain a weight of 18 lb. in water, in addition to its own weight. Dr. Silvester suggests that a large dog or a calf thus used might be able to bring a number of persons safely to shore, and that there are many cases in which this plan of treatment might be applied to man himself, rendering him practically unsinkable. This is a suggestion that may possibly be of service under some conditions, and is

no doubt an addition to the means of saving life at sea: but we question whether more than this can be said about it.

THE DISTURBANCE BY STUDENTS IN THE THEATRE ROYAL, EDINBURGH.

ON Thursday evening June 28th a number of students created a serious disturbance in the gallery of the Theatre Royal, Edinburgh. Seven of these were taken into custody; they were brought before the magistrates and fined. A meeting of the *Senatus Academicus* was held for the purpose of receiving the report of the Committee that had investigated the circumstances attending the disturbance. There is understood to have been some difference of opinion as to the punishment to be awarded, but ultimately it was determined to rusticate the two chief offenders for the present summer session, which closes on July 29th, and for the ensuing winter session; while in the case of the other five students who were convicted the rustication was limited to the summer session.

THE CONTAGIOUSNESS OF PHTHISIS.

THE revival of an old belief, especially when this is due to the discovery of some new fact that apparently supports it, is no new thing in history; and in medicine particularly we find the ideas discarded by one generation reverted to by the next. The doctrine of the contagiousness of phthisis has been held by some from the very dawn of medicine, has been a matter of popular faith in many countries, and yet has been grounded on no substantial basis. To those who wish to learn how the doctrine is supported at the present time we may refer to the opening article in the new *Bristol Medico-Chirurgical Journal*, by Dr. Shingleton Smith, who begins his thesis with the propositions advanced by Dr. Budd sixteen years ago in support of the view that phthisis is contagious. The arguments employed by Dr. Budd then are much the same as those in vogue at present, with, however, some notable additions from recent pathological research—the similarity of the pathology of tuberculosis to that of zymotic diseases, the evidence of actual communicability of phthisis, the geographical distribution of the disease and its introduction by Europeans into countries hitherto free from it, its prevalence in low levels and amongst crowded communities—conditions also favoring the spread of zymotic disease generally. To these and like arguments must now be added the knowledge gained of the infectivity of tubercular material within the body, the inoculability of the disease in the lower animals, and lastly, the crowning discovery of Koch as to the presence of bacilli in the tubercular deposits and ejecta. All these and many collateral points are dealt with by Dr. Shingleton Smith, who also gives the result of his own examination of sputa for bacilli. The arguments in favor of the zymotic nature of tubercle—i.e., of phthisis—are given here plainly and fully, and the reader must weigh them for himself. He will, however, be considerably assisted in his analysis if he first peruses the next article in the journal, in which Dr. Markham Skerrett writes with precisely the opposite tendency to Dr. Smith, and adduces clinical evidence against the contagiousness of phthisis. On his view the bacillus may only be a concomitant (or a result?), but not necessarily a cause of tuberculosis, whilst, further, inferences from the experimental inoculation of animals may be pushed too far. The body of his paper is occupied, in the first place, with the evidence adduced in sup-

port of the contagion theory, and he shows how readily this may be exaggerated, particularly the evidence of transmission through marriage; then comes the formidable array of facts against the theory of contagion afforded by the hospitals for consumption, and the slight liability to the disease amongst those who wait on patients. Dr. Skerritt shows that the necessity for assuming a special predisposition to tubercle places it in a different category from other contagious diseases, and, indeed, differentiates the human disease from that produced experimentally in animals. The appearance of these articles is timely; and although neither writer would perhaps claim that finality has been reached in this question, their readers will see how different the same thing looks when regarded from two opposite standpoints.

THE LORDS AND PIGEON SHOOTING.

THE rejection of the Bill which was intended to put an end to the ignoble practice of shooting trapped pigeons under the guise of sport, but really for "betting" purposes, is not one of those works of the hereditary legislature which will incite sensible people to "thank God we have a House of Peers." We can conceive of many graver acts of opposition to the will of the Commons House of Parliament which would do less to shake the stability of the "Upper" House than this weak and unwise procedure. It is perfectly true, as a contemporary has pointed out, that with hardly an exception the majority which rejected the measure was composed of obscure members of the House of Peers, who have the power to do this wrong simply because they happen to have been born to rule. The true wit and wisdom of the hereditary branch of the Legislature was on the side of the pigeons. As the Duke of Argyll justly observed, "pigeon-shooting is wanting in all those higher elements which make other sports natural to mankind and delightful to the most civilized man." Pigeon slaughtering is precisely the sort of pastime which would commend itself to the instincts of the feeble-minded and unmanly clique of persons who formed the majority of the Upper House. As a matter of absolute fact, the only consideration which preserves the sanction of the law for pigeon-shooting is the excuse it offers for petty gambling. Anything more disgraceful than the betting which goes on at the so-called "clubs" which assemble for the purpose of slaughtering trapped pigeons it would be difficult to imagine. For the session this measure is lost. Next year it will be revived; and then doubtless, with the accustomed cowardice of their House when actively pressed, the peers will pass the Bill. Meanwhile by its rejection they have driven another nail into their own coffin.

SEA-BATHING RISKS.

WE have repeatedly called attention to the risks which beset bathing on the sea shore, whether with or without machines. It is urgently necessary that this most healthful exercise should be placed on a safe footing. Diving in shallow water and venturing out of fair depth of water are acts of foolhardiness against which it is difficult to protect the public. There should, however, be some official on every beach to supply information and take measures for the safety of those who venture into the sea, and this person ought to be endowed with power to compel necessary precautions. In nearly every instance of loss of life which at this season agonizes the public mind, there is cause to regret the neglect of some obvious measure of carefulness. This is a matter for the interference of local authorities. Those who

are really anxious for the prosperity of their particular places of resort should not fail to regard this phase of enterprise as important.

THE SITES OF DIFFERENT MICRO-ORGANISMS.

It is not at all improbable that the localities which bacteria affect may come to play an important part in the study of micro-parasitic pathology. Whatever be the explanation, there is no doubt that the micro-organisms hitherto found have various relations with the tissues. We are speaking of histological structures, and not of the different organs of the body. For example, the micrococci of variola are found in the vacuolated cells of the rete mucosum forming part of the small-pox pustule or papule. The same may be said of vaccinia. Fehleisen has shown that the zoogloea masses of erysipelas plug the lymph-spaces. From a communication recently made to the Société Médicale des Hôpitaux, we find that these particulars have been verified by MM. Cornil and Babes, who have already distinguished themselves in the field of bacterial pathology.

VERBAL BLINDNESS.

APHASIA presents itself under such a variety of forms, and in such complexity of combination, that there can be no more difficult subject in the whole range of neuro-pathology or psychology. We have obviously used the term in its widest sense as synonymous with disorder of every kind of the faculty of employing verbal language. The following case of what M. Kussmaul would term verbal blindness is reported at length, but still with insufficient detail in some noteworthy points, in the *Gazette Médicale de Paris* of June 16th. A man of business, aged thirty-five, was suddenly seized whilst in the hunting-field with right hemiplegia and aphasia. He had been the subject of severe migraine, but with that important exception had enjoyed good health. Consciousness was lost a few minutes after the hemiplegic seizure. At no time was loss or impairment of ordinary sensation detected. Both the paralysis and the loss of speech were on the mend when one day the patient wished to complete a letter which he had already begun, and found to his astonishment that he was unable to read what he had written but a few days before. Later on it was discovered that an inability to read printed matter also existed. The letter in question when compared with one dated three years back exhibited no special difference. In talking only occasionally did the patient substitute a wrong word. When seen by Charcot five months after the onset of the seizure, no important defect remained except right lateral hemiopia and the inability to read. The hemiopia had been indicated by the fact that in attempting to play billiards the ball was seen to be but half a sphere. Acuity, however, in the other part of the field of vision was normal, so that the letters could be seen, though not read. Loss of memory for a certain number of substantives and proper names, including those of the streets of Paris, existed. He did not venture alone in the city because of the last defect. He could write his name, his address, and even a long letter without any important errors, but he could not read what he had written. In order to decipher a word he slowly formed each letter of the term with the tip of his right forefinger, and then the notions furnished by the movements of the fingers came to his aid and controlled the incomplete, insufficient visual impressions. In the phraseology of Dr. Bastian, the defective action of his visual word centres was helped out by the almost simultaneous ac-

tivity of the *kinæsthetic* word centres. M. Charcot has utilized from a point of view of treatment, the help afforded by this *muscular sense*. So much progress was made that whilst at the beginning of his re-education it took 100 seconds to read one line of print, after sixteen days 27 seconds sufficed to accomplish the same task.

"Audi alteram partem."

REMARKABLE CASE OF INJURY TO THE ORBIT.

To the Editor of THE LANCET.

SIR—A very unusual accident came under my notice in practice some time since, and, as I have never seen or read of a similar case, I thought, perhaps, it might be worthy of record in your pages. The accident happened as follows:—One of the rests for supporting the globe on an ordinary gas bracket entered the orbit of my patient, a young girl, a worker in one of the mills here, ruptured the conjunctival membrane, and, being bent or hooked at the extremity, got caught on one of the muscles at the external surface of the eyeball; this it tore from its attachment to the bone, the insertion into the sclerotic coat remaining intact; the body of the muscle lay on the cheek of the girl. Of course, there was nothing to be done but to cut the muscle away as close to its insertion as possible. I did this, enjoined rest of the eyeball, and ordered cooling lead lotions to the eye.

The muscle torn away must have been either the inferior oblique or the external rectus, as both are attached close together at the external surface of the eye near the cornea. From the structure of the muscle at the extremity I should infer that it was the inferior oblique, as its origin is tendinous and by a single head, an arrangement very different from that obtaining in the case of the outer rectus, which is fleshy and biventral. In my case the torn end of the muscle was fibrous, and so corresponded with the inferior oblique. As the patient did not return nothing could be gathered by me as to which muscle was injured from the loss of motion and the strabismus which would inevitably result as a consequence of the destruction of the muscle. It must be presumed that no serious inflammatory action ensued either in the orbit or eyeball from the injury. This is rather astonishing, as the force exerted in the rupture of a tendon must be very considerable, and one would have expected that very serious consequences would have resulted in this case to the delicate tissues of the eye. The very serious and unique character of this accident, and the minimum result of injury to the eye, have induced me to record the case in your pages.

I am, Sir, yours faithfully,
J. W. HAMILL, M.D.

Higher Broughton, Manchester, July 9th, 1883.

THE CHOLERA AND HAGAR'S WELL AT MECCA.

To the Editor of THE LANCET.

SIR—The following correspondence, which speaks for itself, is of such an interesting and important nature at the present time that I send this copy to you in the hope that through publication in THE LANCET the question raised may attract attention, and possibly meet with some practical consideration. In spite of the

action taken in the matter by Sir Joseph Hooker and Mr. Thiselton Dyer, and by Dr. Frankland in his letter to *The Times* less than two years ago, the facts stated below have been apparently quite forgotten, and are in no way referred to among the numerous guesses that are now being made afresh concerning the momentous question of the origin and propagation of Eastern cholera. It may be at least worth while to search for the truth about cholera, even at a lesser depth than at the bottom of Hagar's well. The copy of the letters I send you has been very kindly furnished by Mr. Thiselton Dyer.

I am, Sir, yours obediently,

H. DONKIN.

Upper Berkley Street, W., Aug. 3rd, 1883.

[COPY.]

Royal Gardens, Kew, Nov. 18th, 1882.

SIR—I am desired by Sir Joseph Hooker to forward to you, for the consideration of the Secretary of State of India in Council, the enclosed communications from Dr. Frankland, Professor of Chemistry in the Royal College of Chemistry, South Kensington Museum. The circumstances which have given rise to these, are briefly as follows:—Mr. James Zohrab, Her Majesty's Consul at Jeddah, is an old correspondent of the Royal Gardens. On recently returning to this country he forwarded to Kew a considerable scientific collection of dried plants made by him in the neighborhood of Jeddah. The package also contained two bottles of water from Hagar's well at Mecca. Of these, Mr. Zohrab guaranteed the authenticity, and he expressed the wish that they should be placed in the hands of some scientific man who would take the trouble to investigate their contents. I accordingly communicated with Dr. Frankland, who probably has greater experience than any man living in the investigation of potable water. Dr. Frankland very kindly undertook the examination, and he communicated a preliminary account of the results to *The Times* for September 9th. He now desires that the whole subject should be brought officially under the notice of the Government of India. And looking at the fact that the cholera is now raging at Mecca, Sir Joseph Hooker feels assured that, though the subject is foreign to the strict scope of this department, the Secretary of State will not deem it intrusive that his attention should be invited to the matter.

I am, Sir, your most obedient servant,

(Signed) W. T. THISELTON DYER.

HAGAR'S WELL, MECCA.

DEAR SIR JOSEPH—I have received through you a sample of water from Her Majesty's Consul, Mr. Jas. Zohrab, late of Jeddah, and labelled by him with the following note:—"The well is in Mecca. The water is regarded as holy, and large quantities are annually sent as gifts to all Mussulman countries. Most of the Mahomedan princes, especially those of India, have 'keepers of the well,' whose duty it is to send them annually water from the well." I have submitted this water to analysis, and the results which I append hereto appear to me so important as to warrant me in asking you to bring them specially under the notice of the Secretary of State for India in Council. The water is slightly turbid and has a saline taste. 100,000 parts of it contain in solution the very large pro-

portion of 828.24 parts of solid matter, of which a considerable amount is organic and of animal origin. The water also contains an enormous quantity of nitrates—the usual product of the decomposition of animal excreta. The previous animal contamination calculated from the proportion of nitrogen as nitrates and nitrites shows that the liquid supplying this well contains in a given volume nearly six times as much animal matter as is found in the same volume of strong London sewage. This conclusion is confirmed by the presence of a very large proportion of common salt, one of the chief constituents of urine. The suspended matter in the water consists chiefly of dead bacteria.

In answer to my inquiries as to the surroundings of the well, and the authenticity of the sample, Mr. Zohrab writes me as follows:—"In reply to your note regarding the water from Hagar's well brought home by me, I beg to state that it is authentic. It was brought to me last January from Mecca by a Mahomedan gentleman in whose good faith I have implicit confidence. I may also state that several Mussulmans at Jeddah, who had frequently tasted the water at the well itself, and to whom I showed what I had, assured me it was genuine. There is no difficulty whatever for a person at Jeddah to get any quantity of the water, as the well in Mecca is free to all, and anyone may carry away as much as he pleases. I am not at all surprised at the water being heavily charged with excrementitious matter, and the reason, as I will now show, is evident. The city of Mecca, lying in a basin, contains a permanent population of about 40,000 souls, and annually during the Hadj (pilgrimage) from 100,000 to 150,000 pilgrims, who become residents for periods varying from one week to three months, crowd into it. This vast influx of strangers finds accommodation where it can; the well-to-do rent rooms, the poor live in the streets. The houses in Mecca are generally built in flats to accommodate pilgrims; each flat is provided with one or two badly constructed latrines, and there are from six to twelve of these in each house. These latrines empty themselves into pits dug outside the houses. When these get filled they are emptied into other pits, which are made in the streets or any convenient spot, and then covered over with earth. For the poor, latrines on the same principle are made in and outside the town, and the same method of emptying them is employed. This system of burying foul matter in every direction has been pursued for centuries; it is not, therefore, surprising that the ground in and around Mecca is surcharged with excrementitious matter, which rains (these are frequent in Mecca) carry by filtration into the wells. Hagar's well is not a spring, but its water is supplied by filtration—that is, by rainwater passing down through an overlying mass of foul matter. But there is yet another cause for the pollution of Hagar's well, this is the thousands of pilgrims, diseased or sound, who daily wash beside it, the water they use naturally finding its way back into the well."

Such being the surroundings of this holy well, and the composition of its water, there can be no doubt that here is a most potent source of cholera poison, for the evidence is most conclusive that cholera is propagated by a specific poison contained in the alvine discharges of persons suffering from the disease. Hagar's well, therefore, must, according to Mr. Zohrab's description, constitute an efficient collector of the poison, and it would scarcely be possible to devise a more effective means for the diffusion of this poison throughout Mahomedan countries.

I presume that it would be quite impossible to get this well closed; but in the interests of the

health of Europe and Asia efforts ought to be made to guard the water from this abominable and dangerous pollution. In the whole course of my experience I have never met with a sample of drinking water making even a distant approach to the degree of pollution exhibited by the water of Hagar's well. I remain, yours very truly,

(Signed) E. FRANKLAND.

Sir Joseph Hooker, K.C.S.I., etc., etc.

India Office, S.W., January 3rd, 1883.

SIR—I am directed by the Secretary of State for India in Council to acknowledge the receipt of your letter of Nov. 18th, 1881, forwarding the result of an analysis of water stated to have been taken from Hagar's well at Mecca, made by Dr. Frankland, together with his report on the same. In reply, I am to inform you that a copy of these papers will be sent to the Foreign Office and to the Government of India.

I am, Sir, your obedient Servant,

(Signed) ENFIELD.

PARIS.

(From our Paris Correspondent.)

DEATH OF M. PARROT.

I REGRET to report the death of Dr. Parrot, which took place on Sunday, August 5th, after an illness of two months from pulmonary disease. Dr. Parrot took his degree in 1857, was promoted to agrégé in 1860, and appointed Professor of the History of Medicine in 1876. He was also member of the Academy of Medicine and Physician to the Asylum of the "Enfants Assistés." His body was removed to Excideuil in the department of Dordogne, his birth-place.

M. PASTEUR ON THE ETIOLOGY OF CHOLERA.

M. Pasteur having been solicited to lay before the public the instructions he had given the members of the scientific mission to Egypt to investigate the nature of cholera, now raging in that country, and which was noticed in your annotations recently, has generously complied with the expressed desire of his friends. M. Pasteur prefaced his instructions (of which I send you an abstract copy) by remarking that the precautions hereinafter enumerated relate to those cases where the causes of contagion will be found to prevail in their maximum intensity. These precautions, he added, are instituted under the hypothesis, which he considers very probable, if not certain, that cholera does not enter the human organism by the air passages, but that it does so only by the digestive canal, unless under very exceptional circumstances:—1. Not to make use of the drinking water of the locality in which the mission will be located without having previously boiled the water, and shaken it well, after it has become cold, for two or three minutes, in a bottle half filled; or the water may be put into vessels previously heated, "vases flambés"—that is to say, vessels that had been subjected to air heated to about 150° C. or even more, the higher the temperature the better. The natural mineral waters may be employed with advantage instead. 2. Make use of wine that has been heated in bottles to from 55° to 60° C., and which should be drunk in glasses also previously heated. 3. To make use of alimentary substances only after being well cooked, and fruits in their natural state, but previously washed with water that had been boiled, and preserved in the same vessels in which it was boiled.

or had been transferred into those previously heated. 4. To make use of bread cut up into thin slices and submitted to a temperature of about 150° C., during twenty minutes or more. 5. All the vessels employed for alimentary purposes should also be previously subjected to a temperature of 150° C. or more. The bed linen and towels should be plunged into boiling water, and then dried. 7. The water for washing or bathing should be previously boiled, and, after being cooled, mixed with solutions of thymic or of carbolic acid, the former in the proportion of 1 to 500 parts, and the latter 1 to 50 parts. 8. The hands and face should be washed frequently during the day with boiled water, and to which should be added solutions of thymic and carbolic acid. 9. It is only in cases where the bodies of patients who have died from cholera or their soiled linen has to be handled that it would be necessary to cover the mouth and nostrils with a small mask formed of two pieces of thin plates of metal, enclosing between them a little cotton-wool of not more than 1 centimetre thick, the mask having been submitted to 150° C. only, and renewing the temperature of 150° on each fresh exposure to contagion.

ARTIFICIAL LIMBS.

To the Editor of THE LANCET.

SIR—A considerable number of persons, who have been the subjects of amputation in London and provincial hospitals, and also under the care of various surgeons as private cases, have been examined by me at the Surgical Appliance Society for the purpose of advising what form of artificial limb would be best suited for each particular case. The result of these examinations leads me to think that the surgeon sometimes forgets the future of the patient; he devotes much care to his recovery and the production of a good stump to look at. The surgical authorities advise saving as much as possible, on the principal that the less loss of substance the less risk; accordingly conservatism is carried to an extreme, and operations are performed so as to leave as long a stump as possible. The long stump left in these cases with its large extremity is difficult to fit into the usual artificial case. It would have been better for the patient to have a little shorter stump, and the increased risk would be hardly appreciable. Most of the writers on surgery pass over the question of artificial limbs with scant notice, such as "it is better to leave the application of artificial appliances to the mechanical artist."

The surgeon who performs his operation in such a way as to leave what may be called a workable stump will earn the gratitude of the patient. The cost of the usual artificial limbs is so high that they can only be obtained by the wealthy, and there is constant expense in repairs. Artificial limbs suitable for mechanics, clerks, and laboring men have long been wanted at a reasonable price. They have been obliged to put up with a pin-leg or a hook-arm, which are neither very efficient nor ornamental. Through the kindness of Lieut.-General Maxwell, specimens of the artificial arms and legs invented by the Count de Beaufort were sent to the Surgical Appliance Society with the view of meeting this long acknowledged want. The artificial arm is extremely light, is securely attached, and looks most natural; with it men can perform most of the ordinary functions required of the hand. The artificial Beaufort leg is made in several forms, according to the position of the operation. In a case of amputation above the knee, with a fair stump a man can walk without a stick, and can sit down comfortably without having an incon-

venient projection as in the ordinary pin-leg. In amputation below the knee the artificial Beaufort leg will supply the place of the lost member in a truly wonderful manner, enabling a workman to follow even a laborious occupation. The ordinary bucket legs are very heavy. These limbs are light, the leg weighing about five pounds, the arm twelve ounces. The common pin-leg gives one pound of support; in the Beaufort leg each successive part of the curved foot as it touches the ground becomes a new base of support, and there is less liability to slip. There is less shock in walking, and almost none of the dragging feeling so much complained of by wearers of the ordinary forms of artificial limbs. I have fitted on many of the Beaufort limbs, and strongly recommend them for general use. Moreover, their small cost brings them within the reach of persons of very limited means. These limbs have been in use on the Continent for many years by all classes of people, and are well known and appreciated. I shall be pleased to show models of these limbs to any surgeon at any time, and to give any further information about them.

I am, Sir, yours, etc.,

JAMES THOMPSON, M.D.

Finsbury-circus, July 7th, 1883.

Dr. W. H. BYFORD, Prof. Gynæcology, Rush Medical College, President and Prof. Obstetrics Woman's Hospital Medical College, Chicago, Ill., says: "We have tried the Bromidia prepared by Battle & Co. It is a useful preparation, and fulfils our expectations."

Dr. A. H. SMITH has been elected Professor of Clinical Medicine and Therapeutics at the New York Post-Graduate School, dividing the former chair with Dr. T. E. Satterthwaite, Professor of Pathology and Clinical Medicine. Dr. Alex. J. C. Skene, of Brooklyn, has been elected Professor of Gynæcology, dividing the chair with the present incumbent, Professor B. F. Dawson.

Dr. JOHN S. BILLINGS has declined the offer of the Professorship of Hygiene in the Johns Hopkins University (says the *American Medical News*), for the reason that it is impossible for him to hold this place while he is an officer of the army, and he prefers to retain the latter position and continue his library and indexing work, for the present at all events. It is probable, however, that during the coming winter he will give a course of lectures at the University on the subject of municipal hygiene.

THE HANSOM CAB.—We are glad to see that this comfortable vehicle is coming into favor with the physicians of New York, several of them being now seen in our streets. To the elderly physician especially the Hansom Cab is a great boon. As regards the ease with which it may be entered and left, and the protection which it affords, in all weathers, it is quite the equal of the favorite coupe, while it possesses the important advantage that the pleasure of riding in the Hansom Cab is as great as in an open vehicle, the view being entirely unobstructed. We believe that Messrs. Hincks & Johnson, of Bridgeport, Conn., are the only makers of these vehicles in the United States. They recently constructed one for the use of the great showman, P. T. Barnum, who is certainly a good judge of what comfort in riding is. City physicians would do well to procure price lists, descriptive cuts, etc.

Address to Students.

PRELIMINARY REQUIREMENTS.

It may be presumed that our remarks will be read chiefly by those who have already decided upon medicine as their future profession, by students who at the various hospitals or colleges have to some extent progressed in a knowledge of the laws tending to proficiency in their high calling, or by the newly fledged practitioner only anxious to join in the fight against disease and death. But we would earnestly wish to be heard by those also who have not yet taken what may be an irrevocable step; and to impress upon youths themselves, their parents, and their guardians how important is the issue which sends so many to a certain failure, which could have been easily foretold. The temptation of an honorable and honored profession, and one in which absolute failure, after a diploma is obtained, is rare, where steadiness and zeal are sure of a moderate reward, seems, in these days of hurry, worry, and waste, one which to the middle-class Englishman is hard to resist. The choice of a profession so often depends upon trifling considerations that we might wonder at the number of successful votaries, and be disposed to assert that the haphazard method of sending sons to the various professions or trades can scarcely be improved upon. But, so far at least as medicine is concerned, it should be known to parents and school teachers that its exactions are such as to fairly test the powers of intellects naturally robust and thoroughly trained; whereas the feeble youths unacquainted with the laws of thought, or incapable of their application, soon fall off in the contest, and must ultimately turn to more congenial tasks, depressed by the consciousness of inferiority. Were a little knowledge of the requirements for a hopeful course in medicine appreciated outside medical circles, we should not have those terrible records of baffled effort, of depressed minds, and often of ruined lives indicated in the percentage of rejections at our various universities and licensing bodies. Who can estimate the misery involved in the table of rejections at the College of Surgeons? The average number passing yearly into the profession is but a ghastly shadow of the eager recruits who join the ranks as medical students; and there need be little doubt that many of the shoals which

cause such numerous shipwrecks are shown on the personally constructed chart of every intelligent practitioner. We have before indicated the importance of a thoroughly sound physique as a part of the outfit of every intending student of medicine; but year after year the ranks are thinned by nature's own weeding, and otherwise promising men sink under the weight of study or the worry incidental to examinations. A physical examination by a medical man would be a fitting prelude to even serious thoughts of medical study; and were the examiner to take into account not only the physical condition of the aspirant, but also the hereditary history with regard to lung and brain mischief, an appreciable proportion would be rejected at this best of all periods for the process. There are, too, amid the throng of the preliminary examinations, many boys who on the score of age alone should hardly be admitted. It is distinctly against the ultimate interests of the practitioner to enter for anatomy before he has attained his seventeenth or even eighteenth year, while it is not unusual to find boys of fifteen or sixteen reading the bones or puzzling themselves with the atomic theory. We have known a boy of sixteen to attend, uncontrolled, several cases of midwifery, and that before he had ever heard a lecture on the subject. The three or four years before eighteen is reached can most fitly be spent in the study of those subjects embraced in the "preliminary;" and if it be possible to obtain such an acquaintance with any of these as shall far exceed the requirements of the examining board, and so constitute a life-long delight and a present intellectual exercise, the student will indeed be fortunate. What we want in these preliminary subjects is thoroughness rather than range of study, though the choice should be wide. The boys who dabble in a long list of subjects only with a view to satisfy the least exacting of the public boards have no permanent good for their pains, and in gaining a mere smattering of Latin, Greek, mathematics, etc., their time is all but wasted. It may be taken for granted that the candidate who can only succeed in translating one carefully indicated book of Xenophon's *Anabasis* will find it difficult at the end of his curriculum to run over the Greek alphabet, and certainly this classical language will be neither a help nor a solace in after years. Taking the subjects best fitted to the taste of the youth and his opportunities of acquirement, they should be so far pursued as to become intellectual stock-in-

trade, thoroughly assimilated, and capable of production at any time. It would then matter less whether classics, modern languages, or science should have been studied; the mind has been thoroughly fitted for close application, and its powers have been elicited even at this stage. The schoolboys who swallow their subjects are plucked; those who assimilate their knowledge go on increasing in their strength from year to year. Those who are detected as mere drudges had far better stop short of medicine, as assuredly, where observation and generalization are so much required, they will be found defective. Guardians should save such youths from the destiny which awaits them in the Preliminary, or more probably the First Professional Examination; and as a plain indication of the chances for a boy of mediocre attainments, who chooses a diploma as his goal, we may transcribe the lists for the Primary and Pass Examinations of the College of Surgeons for the past two years:—

		Total.	Passed.	Rejected.
1881-82	Primary.....	1091	744	347
	Pass	666	412	254
1882-83	Primary.....	1119	795	324
	Pass	769	488	281

The fact that during these two years 2,210 men presented themselves for the Primary Professional, and that during the same period only 900 received their diplomas, is full of warning, and affords distinct proof that the preliminary examinations do not form a sufficient barrier against the incompetent, but rather lure them on to subsequent destruction. It would be interesting to find the proportion of students licensed without one or more failures in one or more examinations. While saying all this, however, we do not claim for the would-be medical student more than a sound constitution, a due preliminary training, and a talent for the peculiar course of study that must be his, always remembering that many youths are admirably fitted for other honorable pursuits who show themselves unequal to the many-sided requirements of the successful medical student.

THE CURRICULUM.

Before entering upon a course of study at one of the many Universities or Medical Schools it is essential for future success, with a minimum of irritation and disappointment, that the course of study, the degree or diploma to be striven for, and the time to be devoted to the curriculum should all be mapped out, after the most serious discussion with well-informed friends. It is of course possible that changes may be forced upon a student, however well thought out is his course; but most of the elements for decision are open, even within the limits of our present number, and pecuniary or other social circumstances should have the consideration necessary before the curriculum is entered upon. If a minimum qualification is the only possible goal, the number of classes and even of subjects is considerably reduced, and the usual period of four years' study gives ample opportunity for gaining the knowledge necessary to satisfy examiners. There must always remain a large class of men satisfied with the lowest attainable qualification for legal practice; but, except where insuperable difficulties intervene, we must advise all students worthy of the name that a title implying a more than minimum acquaintance with medicine is a lifelong satisfaction, and one which is gradually becoming more and more esteemed by the public as well as the profession. Fortunately, the days of single and incomplete qualifications are now numbered; the Legislature itself deems the evil one to be crushed.

Those of our readers who aspire to a respected position will ever aim at a course of study and a series of examination much above the legal requirements. Branded as *single* qualifications have become, it should need no Medical Act to ensure that every capable man should show himself trained in all the branches of his art; and it is certain that the amount of public discussion recently given to medical matters has shown the people of this country how inadequate may be the knowledge of men now legally entitled to practice. The higher titles, then, should attract more and more of our average students, and for this purpose it is necessary that the prize should be viewed from the first as attainable. Every man who has facilities for the competition should aim at a degree in medicine. The increasing value set upon this distinction is evidenced by the crowds of students now filling the Scotch Universities, by the recent development of the Victoria University on the same lines, and by the rapid growth of the promising Cambridge school. Though the usual course, even for a degree, can still be accomplished in four years, its increasing extent, both in width and depth, will gradually force upon the Medical Council and the Examining Bodies the desirability of extending the period of study to five years, and every entrant who can now make choice should begin with the distinct determination to labor thus long before accepting a diploma. Already candidates for such distinction as the M.B. of the London University confers are compelled by the nature of the examinations to spend five years or longer in study; and we understand that the proportion of Scotch students who obtain a degree at the end of the fourth year is rapidly diminishing. These facts, then, must be looked in the face, and either the curriculum must be extended or the whole of the less strictly medical subjects excluded, and considered as belonging to the preliminary training. Physics, inorganic chemistry, botany, and zoology should ere this have taken their rightful place, and should no longer be allowed to interfere with the proper work of the medical student. But it must be remembered we have not yet attained to this common-sense order of study, though we may be nearer it than is evident on the surface, and it behoves commencing students to carry out for themselves a thoughtful method, in so far as this is possible, the standing regulations of schools and examining bodies being considered. The present curriculum of study may be divided into three parts or branches; and the subject in each division should be looked upon as constituting a distinct section for intellectual effort, each having its own relative value, but all being necessary for the full equipment of the practitioner of medicine, general or special. The purely scientific subjects should be grappled with at the earliest possible moment; they should be looked upon as valuable in themselves, and as the most fitting introduction to the method of work to be carried on not only by the medical student but by the busy practitioner. A knowledge of man will the more easily be obtained after the study of the animal creation in the class of zoology and comparative anatomy; the physiology of plant-life will accustom the student to processes which he will afterwards the more fully appreciate in the class of human physiology; and without even the trifling amount of chemistry usually carried forward into other work a want would be felt at every turn. The gathering of facts, the methods of classification, and the generalizations on well-ascertained data to which the student here becomes accustomed constitute a fine discipline, without which scientific study is impossible, and he who is enabled to grasp the principles which he may

not have time to elaborate will in after-life find such knowledge of superior value to all his facts. The simple acquaintance with bones, muscles, bloodvessels, and nerves obtained with the aid of the scalpel and text-book in the dissecting-room is the first study to which the average medical student attaches a definite importance; and as his knowledge of function or microscopic anatomy enlarges he gradually finds himself engaged in the most important work of laying a sure foundation for all his subsequent study; he is indeed occupied with the keystone as well as the basis of the structure. Anatomy may be considered as a subject not lightly to be laid aside during the whole period of college life, and no man has yet acknowledged that he has dissected too much. The purely scientific studies being disposed of, the subjects which next most profitably engage attention may broadly be said to embrace the theories and principles upon which all but the most empirical medicine is based. Now is the time when the scientific physician takes shape; when a knowledge of organic function, whether physiological or pathological, is obtained; when the principles, apart from the practice, of medicine and surgery can be taught, and the foundations laid deep and strong for the gradual rearing of a goodly building, the stones for which will be picked up in the last or third stage of the course, when a practical acquaintance is made with disease. The sound physiologist readily profits by the teaching of the pathological laboratory, and, provided with such knowledge, passes easily into an acquaintance with the laws underlying all pure medicine and surgery, as well as the actions of drugs in health and disease. It is perhaps difficult for the student adequately to recognize the importance of teaching, which to his eyes seems but distantly connected with the cure of disease; but it is at the particular stage in his studies which we have now reached when general principles can be laid hold of, and the scientific method made applicable to the whole work of his future career both at college and in practice. The difference is here established between the class of men who subsequently become animated posological tables, backed by a set of "cures" for the various ailments, and the modern ideal physician in whose mind's eye is a picture of disease in which all details are found, and embracing the pathological state as well as suggesting the most rational treatment. With a mind trained to observation and reflection, and a thorough acquaintance with the general doctrines applicable in the healing art, the student will find the third, or directly practical, part of his course an easy matter. He must then devote himself to the steadfast observation of disease at the bedside and in the outdoor department of his hospital; he will accustom himself to accuracy and speed in the use of his senses and the various aids which science has placed in his hands; his constant care must now be given to learning the methods by which disease is met, whether by the physician or the surgeon, and, in short, "clinical" study must now have his chief attention. To a student who knows his anatomy dislocations and fractures are easily understood and remembered; the man who has an intelligent conception of brain function, even as now known, and has handled an atheromatous artery or a roughened valve in the dead house, is easily taught the leading features in a case of apoplexy, and a knowledge of therapeutics at once indicates the appropriate treatment. It is impossible to make an accurate division of the curriculum such as has here been sketched; there must be considerable overlapping of subjects. But the spirit of the method should be conserved, and the result will be less of the perpet-

ual cram and more of the genuine reflection which is characteristic of the cultured student.

THE MODERN MEDICAL STUDENT.

Judging from the descriptions of medical students current during the last, and even far into the present, century, the term must at one time have been anything but complimentary. There is, indeed, no reason to believe that the youth depicted by our novelists could ever be considered as average specimens of those whose training consisted chiefly in "walking the hospitals;" Smollett's revolting sketch—whether personal or not—was merely that of a decidedly objectionable character, who chanced to have as a future a medical career, and the Bob Sawyer of the less remote past bears no closer a resemblance to the average student of to-day. There is still, however, an opinion current that the modern medical student indulges in repulsive pastimes, lives a truly Bohemian life, and assumes, as a supposed evidence of a scientific spirit, atheistic notions in religion, and heterodox views on things in general. These opinions are but the remains of those formerly accepted on all hands, fostered by the ignorant and fanciful sketches of needy or prejudiced writers, and the occasional indiscretions of a real or fictitious medical student. Though the Roderick Randoms are as extinct as the dodo, it is to be feared that first year's men, coming to hospital with the popular notions concerning their class, do sometimes place themselves in circumstances which, in common with their more advanced fellows, they soon come to look upon with shame; but it is certain that the hard work of the regular students and the *morale* of the school are sufficient quickly to eradicate tendencies so dishonoring. As in other classes of the community, there are found among students various grades; and as certain features are characteristic of these, it may be worth while to inquire as to their origin, their continuance, and their subsequent history.

(a) *The Prizeman.*

Perhaps the one most essential element of marked success during a college career is simple industry. The race is not always to the swift; and close observation on the part of teachers elicits the fact that the steady worker of moderate capacity carries off a large share of the honors. The prizeman, too, almost always comes to the front early in the curriculum, by undeviating attention to the subject in hand, from his first entry at the hospital. A first session success is a splendid incentive to future effort. It need not, however, be forgotten that the system of examination by written papers gives an opportunity for "cram;" and thus in many cases the more thoughtful and intelligent student is left behind when detail and numerous facts must be mastered. It requires much thought and judgment on the part of the teacher to arrive at the best method of examination, and not unfrequently he fails to mark by the order of his certificates the merits of the men whom he wishes fairly to judge. As the curriculum advances, and principles as well as particulars must be understood, the mind trained to thought, and intellectually strong, takes a rightful place in the struggle, and finds little trouble in retaining it if moderately diligent. The man who, parrot-like, repeats the fact that the "biceps arises by two heads"—though quite familiar with his Latin—and labors to impress his mind with the truth, may succeed so long as mere memory will serve him, but is out of the race whenever thinking is required. But it becomes yearly more necessary for those who aim at distinction to thoroughly

utilize all the channels of knowledge capable of affording assistance in mastering their subjects, and he who depends upon his lectures and his text-books solely for acquaintance with many matters formerly alone taught in this way, will find himself lamentably deficient. Whenever a statement can be tested by experiment, or conditions shown by dissection; wherever facts can be more forcibly impressed, as they almost always can, by demonstration, the student should greedily accept every opportunity of gaining such practical knowledge. By touch, sight, hearing, taste, and even smell, an acquaintance may be made, with a condition which a long discourse might fail to afford, and the ready and constant use of all the aids to the various senses becomes yearly more and more the habit with all good workers. A time may come when a too great dependence may be placed upon those means of diagnosis which formed no part of the armamentaria of the celebrated physicians of the past; but assuredly we are far from that stage now, and no better or fairer test can be applied to students than the practical use of the stethoscope, thermometer, microscope, laryngoscope, sphygmograph, ophthalmoscope, and other aids, which should be "on the finger ends" of every modern physician. Men who take the necessary trouble to ascertain all that can be known through these channels are unlikely to be suspected of superficial examination, the damning habit which creeps upon so many; and even now familiarity with instruments of precision is expected of all who look for special recognition on the part of their fellows. This, then, is one of the leading characteristics of the distinguished student, that he has called no man master, and received nothing on authority which could be tested by means within his power; and it may be expected that in the future, with such liberal provision on all sides for such inquiries, few except men of this stamp will emerge from class or other examinations as prizemen. It is needless to say that the honors man is usually distinguished for regularity in class and work-room, far removed from the idlers or the drivellers who disgrace their class, or even from those who often excel with the sculls or bat, and seem always bent on preserving the *mens sana in corpore sano*.

(b) *The Average Student.*

During recent years the requirements of students, even for the lowest of the too many qualifications, have increased considerably; this has been met by such earnest effort in every medical school throughout the country, and even the preliminary training and examinations are now so much more satisfactory, that the average student of to-day takes deservedly a higher place than at any previous time. Work has become such a necessity, that to have a fair chance of success at examinations implies a generally exemplary line of conduct, and such industry as is at least respectable. The student who expects to "get through" must now, or in the near future, be satisfactorily grounded in all that relates to medicine, surgery, and midwifery; and medicine, with its collateral studies, now forms such a wide field, that the drones had better avoid all effort at its cultivation. To a man of moderate ability there is no time for idling and trifling, as he is expected during four years to obtain an amount of knowledge which will fully test his powers, and no better help can be given to such than the time-honored but constantly forgotten advice to make the most of his opportunities from the first day of entering his classes. The practical loss of the first session, examinations being then in the somewhat distant future, is the commonest calamity to students, and

it will be generally found that these idle youths are the means of attracting the modicum of opprobrium which still attaches to their class. They seem proud of their unaccustomed title, and show the absence of a needed home-restraint by indulging in follies more childish than vicious. It was noticeable that in a recent outbreak of rowdism at Edinburgh nine out of ten of the disgraced students were of the first year. The manner of life common to medical students, which allows the fullest liberty in a choice of residence, and is unrestrained by college authorities outside the classroom, has disadvantages of an obvious kind. During the young man's first years of city life there is a necessity for guidance, and often for admonition, while the promiscuous gathering of associates is a danger against which all who have an interest in the student should assist in guarding. It is an easy matter to drift into the darker currents, and with our present system no better guarantee against this can be suggested than the fullest use of personal introductions to teachers and friends, who should aim at "attaching" these youths sufficiently to act as a real restraint. The cultivation of exercises outside the bounds of the curriculum is to be commended most fully, and a well-regulated curriculum might with advantage be formulated applicable to the hours necessary for relaxation. The various societies for discussion of non-professional as well as medical subjects, and for the cultivation of music, vocal or instrumental; the boating, cricket, or football clubs, and the many accomplishments zealously pursued by a large number of young men—show how many-sided is the character of the modern student of medicine, and deserve every encouragement. A moderate indulgence in such pastimes does not injure the chances of success at College or Hall, but recognition of the number of failures at the examining boards should teach the anxious student how necessary is steady application to his chief business. Perhaps the most noticeable feature in the average student which requires condemnation is his evident desire merely to fit himself for examination. To this end he deems dresserships and clinical clerkships unnecessary and therefore undesirable; he looks upon compendiums and crams as legitimate possessions, and ignores fuller and complete text-books and special treatises; he imagines there is a royal road to success by means of spurts, and so inclines to desultory study; and the end of all this is the detection by the examiners of the weak links in the chain, frequent rejection, and disgrace. We can scarcely expect a law to be passed against the publication of these traps to the unwary, in the shape of guides to examinations and crams generally, but we can warn the intelligent student against reliance on such broken reeds, and tell him that the road to a degree or license is necessarily toilsome, and not to be taken by such short cuts. A hasty survey of the field may be enough to assist the man who is thoroughly grounded, but the examiner who cannot detect knowledge acquired in such a fashion is unworthy of his position. To the average student, then, good behavior, steady application, and intelligent study are absolutely necessary if the curriculum as laid down by the licensing bodies is to be carried out, and failure in examination avoided.

(c) *The Residium.*

We have already caught glimpses of men in training for the formation of this despised class, but it is unlikely that our words will reach them, and it is advisable to be brief over the unsavory subject. There is, indeed, one division of this class for whom sincere sympathy will be felt, and our re-

marks regarding preliminary requirements were directed towards a diminution of their number. Men are frequently met with in our schools who, having by some means got through the meshes of the net supposed to intercept the unsuitable, prove themselves incapable of reaching a standard of respectable knowledge, and gradually drop off to more congenial work. But it is the chronic nuisance which occasions such evil influences in a school; those helpless, hopeless youths not only rush to certain ruin themselves, but drag not unwilling victims towards their own haunts and damaging customs. The unhappy tap-room *habitué*, the billiard-room frequenter, the well-dressed nincompoop, the moneyed idler, are all dangers as well as disgraces to their fellow students, and a few such men may degrade a whole college. There is in the management of this hindrance to work a decided lack of firmness or perhaps of power, but in any case means should be found for the expulsion of this demoralizing agency from well-ordered universities and hospitals. It is puzzling to know what becomes of these men; they are constantly rejected at examinations, become year by year less familiar with the work of their classes, and better acquainted with their peculiar haunts; they ultimately disgust the friends whom they have deluded, and probably drop into obscurity or infamy. The influence of rejection is by no means an incentive to study in such cases as these, and when that is so the road assuredly leads downwards. The chronic student rarely escapes from his acquired habits or rises higher than the unqualified drudge to some needy and shady practitioner.

THE PRACTICAL ELEMENT IN SCHOOL WORK.

Within recent years there has been no such marked or forward movement in teaching as that which has resulted in the present prominence to all that is practical in ordinary class work. It is to the development of the method of teaching by demonstration which has spread over the schools we must now look for the preparation of a higher standard of student than was possible in the days of continual lecturing and dogmatic statement. The study of medicine must now exert a greater fascination than in the student days of most practitioners; the interest of the whole course, from microscopic botany to practical toxicology, is now sustained by actual demonstration instead of description, and little room is left for authority where all is supposed to be capable of such direct proof. The student should give himself up to the spirit now dominating the method of our schools, gain by dissection, macroscopic or microscopic, and by experiment a thorough mastery over the elementary subjects, and, pursuing the same habit of personal investigation, so accustom himself to the use of all the instruments of precision that long ere the curriculum is closed the habit of direct inquiry may become one of his possessions, as valuable as we have before seen is the thorough mastery of principles when compared with the storage of facts. The recent prominence given to practical teaching, and the still augmenting consequence attached to it, will before long compel a rearrangement of the curriculum by which systematic lectures will hold a less commanding place, or the necessity for a more lengthened course of study will soon be made generally apparent. It would be a most undesirable solution of the difficulty were students to shirk the opportunities for practical study now offered, and as every day the methods of examination are becoming more and more in accord with the teaching, it will soon be found impossible to escape in this manner. While looking with the most friendly eye upon the recent change, it must, we fear, be acknowledged that here and there

endeavors are made to give the system undue weight, but the student has opportunity for discrimination so long as these classes are not compulsory. All earnest workers will see the advantage of practical physiology, pathology, and chemistry, as well as operative surgery, and tutorial teaching in the advanced subjects will be found most useful; but, except where unlimited time can be disposed of, the necessity for practical classes—all of course with extra fees—in botany, zoology, pharmacy, and midwifery is less obvious. While botany and zoology hold a place in a four years' curriculum it is positive cruelty and something like imposition to pitch examinations so high as to virtually compel students to take this extra course, and we are not charitable enough to suppose that in all cases the profits of the class are not a chief consideration. Practical pharmacy can probably best be picked up in a chemist's shop or dispensary—at least, student's speak of this class as largely a waste of time—and midwifery other than theoretic must be learnt in the lying-in room.

EXPERIENCE IN THE TREATMENT OF DISEASE.

In the midst of our modern methods, and with a scientific atmosphere which lends vigor to all inquiry, whether prompted by a desire for utilitarian results or the simple elucidation of the truth, it must not be forgotten that the ultimate aim of all medical knowledge is the alleviation, cure, or prevention of disease. We have already seen how valuable, even in this light, is the study of the earlier subjects; but the foundation being thus securely laid, the keystone can only be placed after every means have been taken to secure facility in dealing with disease. This can be gained in but one way: the book of Nature must be mastered at the bedside, and by regular and continued familiarity with the more trivial complaints met with in the out-patient department and in dispensary and general practice. There is room for a much greater development of the tutorial system in the teaching of clinical medicine in our hospitals, and especially in our larger schools; the elementary work is too often neglected by the visiting physician, either through want of time or inclination, or from the vastness of the field open to him and the superior attractiveness of complex cases and problems; the average student crowding around the popular physician gains little of the intimate acquaintance with the patient's condition necessary to independent diagnosis, and the result is a smattering of high-flown opinion about phenomenal cases, with total inability to deal with the diseases of every day life. We need a large infusion of younger and less engaged men to take in hand the junior student, and teach him how to use his senses and the instruments of precision lying around him; he must be made familiar with urine testing, auscultation, percussion; he should know something of dyspepsia or diarrhoea before troubling himself with the "splendid cases" of a later experience; prescription writing and case-taking should constantly exercise him, so that with confidence he may go forward upon what will, with all his aids, be found a thorny and difficult path. It is only in small groups that students can be adequately trained to this routine work, and even then they must have the closest individual attention; so that physicians of the experience and position of those constituting the visiting staff cannot reasonably be expected to engage in such drudgery, and are entitled to be relieved of the work. Sent forward from such tutorial classes the student is enabled to profit by the bedside demonstrations of the physician or surgeon, and his wisdom will be shown by giving due importance to both methods. It should be the aim of

all to obtain the advantage of a dressership, and, in due time, a clerkship in the surgical and medical wards. Such opportunities should be looked upon as essentials, and in a well-managed hospital a large proportion of students will be so employed. Though the cases allotted be few, the close observation necessary and the feeling of responsibility engendered are lessons of the most valuable kind, such, indeed, as can be obtained in no other way. It will be found that the men of our schools who afterwards become house-physicians or surgeons have been distinguished by their constant attendance and occupation in the wards, and they are thus fitted for the almost inestimable advantages they enjoy in securing the prize of residence. No other position open to a junior practitioner can offer the same facilities for obtaining the best kind of experience—thoughtful and well directed—as the position of resident in a well conducted hospital, especially where teaching is carried on; and, at whatever pecuniary or other immediate sacrifice, such a post should be striven for by men who would know their work. It may be that residents give too much heed to the graver cases, and fail to observe the commoner ailments they will afterwards be expected to treat, yet they cannot avoid vast benefit from their fortunate position. But all men cannot be supplied with these advantages, and, whether in the pursuit of knowledge or for other reasons, a considerable proportion seek to gain the required experience as assistants to general practitioners. We would warn students against the dangers of endeavoring to assume full medical functions while yet unqualified, and with an unfinished curriculum. Such a course too often ends in the indefinite postponement of classes as well as examinations; the supposed advantages of experience do not accrue, and the only result is a slipshod method of treatment difficult to be got rid of, wholly unscientific, and empirical. It is a mere meeting of symptoms, not unfrequently a serious injury to the patient, and generally a species of deception. The system now condemned, though extensively practiced, is capable of a limited good, and an unqualified youth may gain a knowledge of dispensing, bandaging, and other elementary matters, besides experience in the "management" of patients, which will stand him in good stead afterwards. Such aims would be legitimate; but the employment of unqualified assistants as now carried out is hurtful to the zealous student, unfair to patients, and degrading to the profession. It is far otherwise when qualified men are employed; in their case a year or more of work under an experienced practitioner may be of the most signal service, and the majority of graduates or licentiates will find such training afford readiness in dealing with various classes, acquaintance with minor maladies, experience in midwifery, and that confidence and suavity in the treatment of patients which can hardly be obtained in any other way. When it is possible, choice should be made of a situation where facilities for special studies are available. The newly fledged practitioner should bear in mind that he is still but a student, and he will be fortunate indeed if his principal still regards himself in the same light. It is of course obvious that this period of advanced pupillage will have the highest value if spent under a master who avoids simple routine and devotes appropriate thought to individual cases. Daily discussion on these will serve the highest purposes. The haste to commence practice so soon as a diploma has been obtained is an error common to most men; the student, by the simple possession of the parchment, deems himself equal to all emergencies; but we venture to say that the first case of placenta

prævia or puerperal convulsions is likely to cause a rude awakening.

SPECIAL STUDIES AND PRACTICE.

The ever-widening area of medical knowledge, attended as it has been by an almost stereotyped curriculum, has now reached such an extent that an acquaintance with many diseases, absolutely essential to the well-trained practitioner, can only be attained by special effort. It has become necessary to exclude from the course of medicine all consideration of mental diseases, and it is but seldom the student is made acquainted in the regular course either of medicine or surgery with the important diseases affecting the skin; the lecturer on surgery feels he has enough to do in the one hundred lectures allotted to his subject to even hurriedly glance at the principles and practice of general surgery, or what is now known as such, the consequence being that the student too often loses the opportunity of learning anything about ophthalmic or aural diseases. It is a melancholy and even shameful reflection that our system of teaching and examination allows the possibility of men being licensed as fully qualified practitioners who are incapable of intelligently dealing with diseases so common and so important; the only satisfactory thought in connection with the subject is that the outlook is more hopeful, that in the near future these so-called "special" courses will be embraced in the ordinary curriculum, which must be extended to receive them, and examining boards will look upon a knowledge of such subjects as essential. We repeat that the time of the medical student is now fully occupied, and another year is urgently needed that his education may be both complete and thorough. Herein lies the hope of crushing the wretched and increasing quackery which branches off into all conceivable by-ways, and under the specious guise of special study and aptitude entices a credulous public to place confidence in men who, on their own showing, ignore the fact of the complexity of the organism and dependence of special diseases on general conditions. We have almost reverted to the manners of the ancient Egyptians, who had "doctors for each disease, and that disease only. Every place was full of doctors—some for the eyes, some for the head, some for the teeth, others for the belly, and others for secret diseases." Indeed, if this last is a category of specialists, we have already gone far beyond these early efforts, and the special hospitals in London alone expose an amount of charlatanism distinctly opposed to the more legitimate work here indicated. In large tailoring establishments we believe the custom exists of leaving buttonholes to one set of workers, and possibly threading of the needles to another; but though the method works well in such instances, the plan of the tailor can only be imitated by scientific physicians if willing to be considered as the needle-threaders in the profession. Unfortunately, quackery of this kind pays, and so long as that is so the profession must be dragged in the dust, legitimate hospitals starved, material for clinical teaching lost, and patients sacrificed through the ignorance of men whose therapeutic vision is of the most limited character. But we must not forget that the rank and file of the profession are responsible for much of the success of this unfortunate development, as they too often support men of the class referred to, ignoring the claims of the many accomplished physicians and surgeons attached now or formerly to general hospitals, but teaching some so-called special subject as a branch of legitimate study. It must also be remembered that there are branches of practical medicine or surgery, such as mental or eye dis-

ease or gynecology, of such width, requiring such manipulative skill as can only be obtained by practice, or demanding so much personal attendance upon cases, that it is of advantage, alike to the profession and the public, that men should be found to devote their lives to their pursuit. But a sound ophthalmic surgeon must have as a groundwork a thorough all-round knowledge of medicine. The gynecologist and asylum physician should have experience in general practice, whereas the peddling specialist usually has neither. Let our students, then, approach the study of the various subjects dealt with below with the feeling that an acquaintance with these is as necessary as a knowledge of pneumonia or fractures, and that they have only a right to any special place from the fact that they are crushed out of the courses now composing the curriculum. An extra year of study would suffice to obtain a good working knowledge of these organic derangements. The study should, in all the cases, be chiefly clinical, and we trust ere long to see a course of study, compulsory throughout the three kingdoms, which will be drawn with a view to the inclusion of these misnamed specialisms and the suppression of overgrowth in the crop of specialists. A glance at the headings of the remaining paragraphs in this address will be enough to indicate the time at which these studies should be taken. As branches of medicine and surgery they can only be taken when the general principles have been mastered and some experience gained in hospital practice; they should, in fact, be taken in the last year of the curriculum, and, if work for such examinations as are now held is pressing, the young graduate or licentiate should not fail afterwards to spend some time in their pursuit.

DISEASES OF THE EYE.

Among the several special studies to which we must ask the attention of the student, ophthalmology has an undisputed pre-eminence, and the sternest opponents of the modern development, which finds in every organ not only a subject for particular study, but an opportunity for special practice, recognize the importance alike to the public and to the science of medicine of the work carried on by the many distinguished oculists in this and other countries. But even here it may be noticed how much accomplished physicians, known in far other fields, have done to prove once more that the special study of organs can only be advanced by men who have cultivated the whole domain of medicine. There is no more marked feature in modern medicine than the enormous and growing importance rightly attaching to the ophthalmoscopic symptoms in general diseases, especially those of the arteries, and in affections of the kidney or brain. Nothing more intensifies the importance of gaining a thorough knowledge of the physiology and pathology of the orbital contents than to feel, as every student should, that such work, besides its most obvious use in dealing with diseases of the eye, is necessary to a due consideration of the earlier changes in Bright's disease and other serious disorders. Dr. Gowers, in the preface to his excellent work "Medical Ophthalmoscopy," says: "The condition of the fundus should be systematically described in medical case-taking." Alas! how few of our advanced students can do this; and of these few how very small a proportion carry this knowledge into practice, for "when the student, as is now too often the case, only succeeds in seeing the optic disc just before he leaves the hospital, his knowledge of the use of the ophthalmoscope in most cases ends with this." Only those who have made the ophthalmoscope their ally know how valuable it is in the solution

of many of the difficult problems that are constantly meeting one in the practice of medicine. Practice in the use of this instrument should be gained early in the course, say in the third winter, that the student may from that time in the *general wards* be enabled to profit by its revelations; but there is some difficulty as to who should be the teacher at this initial stage. It is, of course, essential that the professor of physiology should have much to say about the organ of sight, but we question if he is the best guide to more than the "mere smattering," almost completely valueless afterwards to the student, for which he alone has time. The same may be said of the lecturer on surgery. Left to one teacher, who devoted himself specially to the subject, the grounding in ophthalmology would be so thorough that to the student it would be one of the most pleasant and useful accomplishments, and he would continue his studies, as occasions occurred, throughout his final summer and winter in hospital. In the empire of medicine, ophthalmology is a colony that has not yet been able to assert itself and has not the position it deserves. True, it is now dawning upon the powers that be that it is a more fruitful region than was supposed, and that its supplies are requisite for the prosperity of the few large colonies hitherto attracting the talents and attention of our professional rulers. The day is not far distant when ophthalmology will hold a very different position in every well-equipped school from what it does now. It is unnecessary to urge the importance to our eye patients of having the advice of men well trained in their work; but we may warn students how damaging may be the results of an apparently simple error in treatment. Let any thoughtful surgeon try to conceive of the misery, the blighted lives, the hopeless future of those infants improperly treated for ophthalmia, and he will urge every student with whom he has influence, and every examining board too, to give increased attention to such diseases. It is not expected that every practitioner should be an expert in the removal of cataracts or in performing iridectomy, but assuredly no one should possess a diploma who is incapable of treating the more common diseases, of knowing the risks arising from the most uncommon of these, and of detecting the point at which his own knowledge fails and a more experienced practitioner should be consulted.

DISEASES OF THE EAR.

It is fortunately no longer a necessity that men desiring an acquaintance with diseases of the ear should journey to the Continent or to particular centres in our own country in quest thereof, as the importance of this study has now been so far recognized that means for its pursuit are provided at all our medical schools. Those who wish the fullest instruction in this, as in other special subjects, will doubtless still avail themselves of the opportunities offered at some of our own large hospitals and at those of Berlin, Vienna, Paris, and Heidelberg, as it is of the utmost importance not only to know the views but to watch the practice of the masters. Now-a-days, however, there is no necessity for ordinary students going far afield for their knowledge, and there is no apology for any man with such splendid facilities ready to his hand if he remains ignorant of a most important group of morbid changes. It is time, indeed, for the reproach to be wiped away that in this country, the cradle of scientific aural surgery, the country of Wilde, Toynbee, and Hinton, the knowledge and skill requisite for the successful battle with these common diseases should still be confined to a small minority of the profession. Remembering, too,

that it is forty years since Sir William Wilde, by the publication of his "Practical Observations on Aural Surgery," gave the deathblow to the antiquated theories and absurd practice which up to his time had held sway, it seems strange that a halo of mystery should still surround these diseases in the minds of many common-sense practitioners. By an intelligent application of anatomical facts, a sound physiology and pathology and rational therapeutics, Wilde was enabled to clearly demonstrate the fact that the great majority of ear diseases have an inflammatory, and not a nervous, origin. This was the grand generalization which broke down mystery and empiricism, and allowed of the application of the same well proved physiological, pathological, and therapeutical principles which were constantly used in other investigations to be brought to bear upon the diseases under consideration. Students and practitioners should be made to know that about 75 per cent. of diseases of the ear are due to inflammation in one form or other, and are therefore for the most part curable in their early stages; while neglect to follow rational principles in treatment or adopt a do-nothing policy often ends with the most terrible consequence to life or happiness. Deaf-mutism in the young, deafness of various degrees at all ages, cerebral meningitis and abscess, pyæmia, and fatal hæmorrhage are a few of the risks run in neglected cases. These consequences are in the majority of cases preventable, were means taken to avoid the extension of the inflammatory process from the naso-pharynx, from which it usually spreads; and it is worthy of emphatic note that this pharyngeal catarrh occurs idiopathically or in such diseases as scarlet fever, diphtheria, measles, and small-pox—exactly in that class of ailments, in almost all cases, treated by the general practitioner. Facts like these should induce every student of medicine to fit himself for dealing with such diseases. The difficulties are not great; the treatment in the early stages exceedingly simple; the risks avoided by successful treatment almost incalculable; and there is hardly anything more gratifying to the practitioner than the bright glance of satisfaction in the face of a patient who, rescued from the terrible curse of deafness, once more hears the voices of friends and the harmonies of sweet music.

DISEASES OF THE THROAT.

Accuracy in diagnosis, success in treatment, and even a knowledge of the physiology and pathology of laryngeal diseases may be said to be such a modern development that the middle-aged practitioner in his student days could obtain but a rough idea of these troublesome and often fatal ailments. Diseases of the throat, so far as they are included in pharyngeal affections, were open to the observations of ordinary surgeons, but until the truly magic mirror was introduced all was guesswork among the numerous diseases beyond the reach of the unaided eye. The genius and necessities of Senor Garcia as early as 1855 had allowed of a reflection of the throat being obtained, but it required further development in the skilful hands of Professors Throk and Czermak before we had the present laryngoscope, whose revelations have almost equalled those resulting from the marvellous invention of Helmholtz. Instead of a prolonged, labored, and often incorrect reasoning, we have now the aid of sight in determining diseased states; and the practical surgeon was not long in so benefiting by the advantage as to entirely revolutionize the surgery of the region. Perhaps none of the modern instruments of precision have been of such practical value in the treatment of the diseases in whose diagnosis they have assisted as the

laryngoscope, as by its use the whole vocal mechanism and higher respiratory tubes have been so exposed as to lie within easy reach of the trained hand, guiding the different aids to the surgeon which are supplementary to the laryngoscope itself. Tumours and foreign bodies are removed with celerity, the inflamed or ulcerated surface can be directly dealt with, and the surgeon is literally within touch of the conditions against which he must war. Nor is the invention of slight use to the physician, who by its aid localizes the paralysis which renders phonation difficult, is assured of the central spot where disease is making way, and can actually see the effects of the spray upon such ulceration as occurs in phthisis or syphilis. The student will find his time well spent in the throat clinique, now happily found at most of the general hospitals, and even a few weeks of close clinical study will assist much in mastering the cases to be seen in general practice. Though it is not expected of the general practitioner that he will readily undertake the extirpation of the larynx, he should obtain such a thorough facility in using the laryngoscope, forceps, syringe, probang, brush, tracheal tube (the last but recently recommended by Macewen), and guillotine or scissors as will allow, not only of the detection of any disease, but the treatment of most.

DISEASES OF THE SKIN.

The skin under a diseased aspect is commonly enough regarded as a highly perplexing field of observation to the student of medicine, and it appears so little inviting that a large number of practitioners may be said to be truly ignorant alike of the etiology, classification, and treatment of skin affections. Before the days of specialism in this department, the student was treated to some remarks on the subject either in the course of medicine or of surgery, and so obtained such a knowledge of dermatology as enabled him afterwards to prescribe indiscriminately the use of arsenic and the inunction of sulphur; but now that recent study and observation have raised these diseases to a specialty, they are simply ignored by not a few as entirely optional. Thus the very advance of knowledge has proved a hindrance to the average student, and it becomes necessary to indicate the importance of the study to the fully equipped practitioner. To leave the management of skin diseases in the hands of specialists, or, what is far worse, to continue to treat such affections without acquaintance with their pathology and retinal therapeutics, is to abrogate the functions of the physician and descend to the level of the quack. We have surely reached a stage when at least a knowledge of the commoner diseases should be expected from the would-be practitioner, when all chronic eruptions should cease to be designated "eczema," and when the necessity for local or general treatment should be at once recognized. How often does it happen that after many months of arsenic or other routine treatment the patient finds that time, money, and suffering have been alike wasted, and that his ailment is parasitic? Liability to these inglorious mistakes should teach the student to avoid their possibility, and even on the most selfish grounds he should desire a knowledge which may easily place him in a favorable position among his fellows. A leading attraction to the study of skin diseases, and the greater reproach in case of ignorance, is the fact that they can be so well observed and so easily mastered by systematic clinical study. We say clinical, of course under a teacher, as we do not envy the man who attempts to read up skin diseases, however beautiful the plates. The variety in classification is most puzzling to the student of books; yet an

able teacher will demonstrate *his own* classification with perfect lucidity, and to this the learner should lean till a thorough familiarity is obtained with one method. After this he may more fully consider the basis of his teacher's arrangement, and possibly reject it as less scientific or less practical than that of another authority. It is, we believe, this initial difficulty which frightens off many willing students; they leave before an interest in the work is secured. It should also be observed how very common are cases of skin disease, and as a further encouragement to the overworked student it may be mentioned that the practice of dermatology does not require the aid of complicated special instruments, or peculiar manipulative skill in the use of them. Moreover, skin affections occur during the existence of other diseases and in close connection with them, so that neither can be understood without a knowledge of both. A broad and scientific study of general medicine is a *sine qua non* to the accomplished dermatologist.

MENTAL DISEASES.

Of late years there has been a greatly increased amount of attention bestowed on the department of psychological medicine, and there are now few schools without a lecturer on mental diseases and abundant clinical material near at hand. It is fortunately becoming more and more common to view insanity as the result of physical change; the mystery which enshrouded the study is gradually clearing off along with the rigid seclusion which marred the practice, and year by year we come nearer the time when acute cases will have home or hospital treatment just as circumstances may determine. The feeling of hopelessness and disgrace attaching to disease of the brain, functional or organic, will tend to disappear as the medical profession begin to look upon such afflictions in the same manner as upon other serious maladies. But all this can only be possible when the medical student applies himself to the study of mental diseases in the same serious manner as those of organs other than the brain. The importance of psychiatry to the practitioner is evident when it is remembered that in this country alone about 80,000 of our fellow countrymen are deprived of their personal liberty upon certificates granted in most cases by the general practitioner; and while it is manifestly impossible that the profession as a whole should have a complete knowledge of these diseases, scarcely obtained by a lifelong study, each individual member should be able to discriminate between those cases that he is in duty bound to treat to recovery at home and those that ought to be relegated to the asylum (hospital) for treatment. But how is a practitioner untrained by the observation of the various mental aberrations to deal even with the primary question of sanity or insanity, or discriminate between the various phases of mental instability? It is part and parcel of the lingering superstition of former ages, when insanity was wrapped about with difficulties and degradations, that calls upon such a man to decide off-hand as to the mental state of his neighbor, as if it were a question easier of solution than any affecting his bodily condition. The insurance certificate granted by an individual who had not been trained in the use of the stethoscope both in health and disease would be scarcely one whit more anomalous than the lunacy certificate of one unschooled in the facts of mental physiology and pathology.

DISEASES OF WOMEN AND CHILDREN.

Anyone possessed of three months' experience in general practice has already become aware that the vast majority of his patients is made up of

women and children, and that the passport to success has been provided as soon as the wives and mothers are satisfied that the practitioner is entitled to confidence. Looking forward, the junior practitioner satisfies himself that the subjects of his life's work are often the occupants of the cradle; looking back to his student days, he finds that children's diseases were conspicuous by their absence from the curriculum, and almost as little seen in the hospital. The junior, again, is consulted by a woman presenting a variety of perplexing symptoms; she knows herself, though she has some delicacy in alluding to the subject, that the womb is at fault, but even the commonest displacement is unrecognizable by a man who has not been taught concerning diseases of women, and the disappointed applicant is probably dismissed with a tonic. It need scarcely be added that she does not return. Our student readers may well ask, Why are our curricula so arranged? In many of our larger schools lectures have within the past few years been advertised on these important subjects, but these have been attended by only a limited number of the best students, and so long as the course remains optional the teacher must address a beggarly array of empty benches. The theory is that gynecology and diseases of children are included in the course of midwifery; but it is obvious that when this is limited to fifty lectures there is absolutely no time for their consideration, and in the universities where one hundred lectures are compulsory only a few of these are devoted to diseases of women, while diseases special to children are totally neglected. In a course of one hundred lectures it should be possible to give twenty-five to diseases of women, and from these a fair theoretic knowledge might be gained; but children's ailments, now so completely neglected, demand a separate course, and students who wish to take an intelligent position as family practitioners should find their knowledge in a less experimental manner than is common at present. There can be no doubt that the regulations of the Divisional Boards will require a new acquaintance with these important subjects; but, whether compulsory or not, a knowledge of at least the commoner diseases should be obtained as the surest road to pleasure and profit in the practice of our profession.

In conclusion, we may observe that our hurried sketch of the special subjects of study is supplementary to our last year's remarks on the Curriculum. We then discussed at some length the ordinary and compulsory subjects, as well as the important speciality which concerns itself with the Public Health; and to these remarks we would again refer our readers. Neither in the study of the ordinary curriculum nor in that of the special studies would continued pressure upon the student be necessary, were it kept steadily in view how all-important and responsible are the functions of the humblest practitioner of medicine. The least accomplished in our profession may have a responsibility upon his shoulders which the highest among his fellows feels to be onerous; life or death is, humanly speaking, in his hands. Let students and practitioners but think often of this aspect of their work, and every effort will surely be made that we may fight and war against disease, and not unfrequently against death itself. We may, too, remind the students of natural science, dealing with ascertained facts and demonstrable principles, that such studies may wean the mind from the contemplation of the Unseen, and tend to shut out the highest thoughts of which man's mind is capable. Let not the supposed opposition between science and religion occupy a thought, until, at least, a wide scientific knowledge

has been obtained; when in all likelihood attempts to solve the insolvable will appear a useless labor. The eloquent words of Professor Gairdner's last introductory address may fitly close these remarks—"Finally, *ora et labora*. Look for the blessing from on high. And if modern science seems, at times, to wean your minds away from God, look again, and look further and yet nearer, till in the reign of law you can perceive a truly divine order; in nature a living force behind nature; in the mystery of your own will the faint image of a higher will than your own, neither less nor more mysterious in its essence; in the endless descent of species, whether by evolution or otherwise, the infinitely multiplied reflection of a relationship to Him, who, while He is the Father of our spirits, and the framer of our bodies, is also 'nigh to every one of us,' the Father of all the families of the earth, from everlasting to everlasting."

ON BOOKS.

It has been customary with us for some years past to include in this number a slight sketch of the literature which is at the disposal of the student in medicine at the present day. Since we commenced that practice many new text-books have appeared, and in some subjects these more modern candidates for the favor of students bid fair to displace the old. In revising what was written on this head a few years ago, we shall not omit what was said of the well established works, some of which appear in new editions almost every year; but we shall also endeavor to notice those additions to literature that seem to us likely to obtain a permanent place.

Chemistry.—Barff, Roscoe; Williamson, Attfield, Fownes; Miller, Roscoe, and Schorlemmer. Of these Professor Barff's "Introduction" is suitable to the beginner, but its scope is too limited for the requirements of any of the medical examining boards. Roscoe's "Elementary Chemistry" travels over the whole range of the subject, and will, if thoroughly mastered, prove more than sufficient. The like is true of Fownes's well-known work, which has been brought up to the modern standpoint by recent editors. For a compact but clearly reasoned book, the student cannot do wrong if he prefer Williamson's work; and those who have time at their disposal, or are ambitious of university honors, the work of Miller, or the last-named on the above list, may be consulted or read.

Practical Chemistry.—Odling, Bowman, Attfield. These books are each of them useful to the student who has not the advantage of personal supervision of his work at the hands of the teacher, or their perusal may profitably be undertaken in conjunction with the practical study of the subject.

Natural Philosophy.—Newth, Ganot; Deschanel, Thomson, and Tait; Balfour Stewart, Tyndall. In this subject, which is required for the "preliminary scientific" examinations, but does not enter into the ordinary curriculum, some of the pleasantest books to read are Ganot's *Physics* and the works on Heat, Sound, and Electricity, by Prof. Tyndall—these latter being books that may be read in hours of comparative leisure, for they are penned by one of the clearest expounders of scientific truths extant. Similar subjects are dealt with in Deschanel's treatise, which may be obtained in separate parts; and Balfour Stewart's work on Heat is widely recognized as one of the best in the language. The large "Natural Philosophy" of Thomson and Tait can only be regarded as a work of reference for most students.

Botany.—Cooke, Silver, Oliver; Balfour, Bentley, Sachs. *Atlases:* Bentley and Trimmen and D. McAlpine. Several works are to be had of an elementary character; that of Mr. Cooke on "Structural

Botany" or the little "Outlines" of Dr. Silver are good. Oliver's "Elementary Botany" has met with well-deserved success, and recently translations of some foreign works have appeared. Balfour's work has long been a favorite, and Bentley's is also much read. Messrs. Churchill publish an excellent Atlas of "Medicinal Plants," under the joint authorship of Professor Bentley and Mr. Trimmen—a work which should find a place in the library of every medical school; and Messrs. Johnston, of Edinburgh, have recently published a useful botanical Atlas by D. McAlpine, containing representations of the leading forms of plant life.

Zoology and Comparative Anatomy.—Nicholson, Huxley, Rymer Jones, Gegenbaur; Flower, Rolleston, Huxley and Martin. For practical work in this subject no better guide could be mentioned than the last-named, and of a severer class is Prof. Rolleston's "Forms of Animal Life." In systematic zoology the various works of Prof. Nicholson have been very popular. They have replaced the well-known text-book of Rymer Jones; and those who wish to go deeper into the subject should not fail to read Prof. Huxley's "Vertebrata" and "Invertebrata." Bell's translation of Gegenbaur's manual serves to complete a list of writings on a subject upon which a few years ago English literature was very defective, and candidates for University degrees could not do better than make this their text-book. Prof. Flower's "Osteology of Mammalia" is the only work of its kind, and its study would add much interest to the dry details of human osteology.

Anatomy—Systematic: Quain, Gray, Wilson. **Practical:** Ellis, Holden, Heath, Ledwich, Cunningham. **Osteology:** Ward, Holden, Morton, Wagstaff. **Arthrology:** Morris. **Regional Anatomy:** Holden, Smith, and Walsham. **Plates:** Ellis, Godlee, Braune, Sibson. In this subject, which occupies so much of the student's time in the first two years, there are very numerous works. For the latter purpose the most complete and trustworthy is Professor Ellis's *Demonstrations in Anatomy*, which has stood the test of many generations of students, and is apparently as much appreciated as ever. Similar excellent guides are the smaller works of Heath, Holden, Ledwich, Cunningham and Carrington. For the systematic study of the subject, Gray's *Anatomy* has long been a favorite, and holds a well-deserved place in the estimation of students; whilst the book which has obtained a world-wide reputation is Quain's *Anatomy*, the representative work of anatomical science in England. Mr. Reeves has lately produced an elaborately illustrated work on *Human Morphology*, which deals with some of the more speculative regions of anatomy. Of the books that have been written upon Osteology, the most exhaustive is undoubtedly Ward's; but Holden's work is perhaps much more widely read, and it is very excellent. The work of Dr. Humphry, of Cambridge, on the *Human Skeleton* is useful alike to the anatomist and the surgeon. The only work specially devoted to the anatomy of the joints is that by Mr. Henry Morris, which may be consulted with advantage. Valuable for the assistance they afford in recalling the parts dissected, and very useful therefore when the student cannot be engaged in his practical pursuits, are the excellent "Plates" of Ellis and those in the Atlas of Mr. Rickman Godlee. In the department of regional anatomy there are the plates of Professor Braune, with English text by Mr. Bellamy, and Sibson's work on *Medical Anatomy*; whilst smaller works dealing with "Landmarks" are those of Holden, Smith, and Walsham.

Physiology.—Huxley; Kirkes, McKendrick; Marshall, Foster, Hermann, Carpenter, Flint. To those who come to a medical school without any

previous knowledge of the subject, no better book to begin with can be recommended than Professor Huxley's elementary work. But this, of course, will not suffice for the whole education of the medical student in this most important subject. The well-known text-book of Kirkes is, of all the works on this subject, by far the most popular, and has run through many editions. Almost as popular, but less attractive to the general student, is the admirable text-book by Michael Foster, which it is incumbent upon the aspirant for higher diplomas to read. Of the same scope as Kirkes' may be mentioned the manuals by McKendrick, Marshall, and Küss; whilst Carpenter's large work has always maintained a high position. The works of Hermann and of Flint have also obtained a well-deserved position in this country. Upon *Physiological Chemistry* the student will find a useful guide in Dr. Ralfe's practical work, and a book by the same writer is promised in Cassell's series, though for a fuller study the larger work of Professor A. Gamgee must be used.

Histology.—Quain's *Anatomy*, vol. i.; Gray's *Anatomy*, Introductory Chapter; Klein; Schäfer; Rutherford; H. Gibbs; Stricker; Klein and Smith's *Atlas*. A fairly exhaustive account of histology is to be found in some of the books mentioned in the last section, but for the most complete treatise on the subject Quain's *Anatomy* continues to hold the first place, the large work by Stricker (Syd. Soc. Ed.) being necessarily too exhaustive for the ordinary student. In the newly projected series of student's manuals, now in course of publication by Messrs. Cassell, there is one volume devoted to Histology by Dr. Klein, which is certain to become a great favorite with students. Professor Schäfer's work is the most thorough guide on the subject of practical histology, and Rutherford's "Outlines" are excellent; and so is Dr. H. Gibbs' little work.

Practical Physiology.—Power and Harris, Foster and Langley, Sanderson. For laboratory guides the two first-named are sufficient, and the larger "Handbook" edited by Dr. Sanderson should be referred to for further details.

Materia Medica and Therapeutics.—Brunton, Thorowgood, Milne, Farquharson, Garrod, Scoresby-Jackson; Wood, Phillips, Ringer, Waring, Fothergill, Neligan. In *Materia Medica* Dr. Garrod's, Neligan's, and Scoresby-Jackson's works are good, as, of smaller size, are the compendia of Thorowgood, Royle, Farquharson, Owen, and Milne, whilst the "Tables" of Brunton are intended to facilitate the student's labor in this somewhat arid subject. Wood's and Phillips's works are both of them of a high class, the best, perhaps, in the language; they deal largely with the physiological action of drugs. Upon the more interesting subject of practical therapeutics, that which has been most widely read is Dr. Ringer's handbook; and the works of Dr. Waring and of Dr. Milner Fothergill also abound in useful hints and suggestions.

Medical Jurisprudence.—Guy, Taylor; Tidy, Ogston. In this subject the books most suitable for students are Taylor's *Manual* and Guy's "Forensic Medicine," which embrace all branches of the subject; but Taylor's "On Poisons," and his larger work on "Medical Jurisprudence," may profitably be referred to; as also the work recently written by Dr. Tidy. The interesting lectures of Dr. Ogston form a recent and useful addition to the literature of this subject.

Public Health and Hygiene.—In Dr. Wilson's work the student will find most of the information he requires, but the standard work of Parkes, which has been edited by Dr. De Chaumont, is one that must not be forgotten.

Medicine.—General: Tanner, Roberts, Bristowe, Carter, Charteris; Aitken, Niemeyer, Flint, Watson; Reynolds, Trousseau. *Nervous Diseases:* Wilks, Charcot, Althaus, Hammond, Bastian, Rosenthal, Gowers, Buzzard, Ross. *Diseases of the Heart:* Walshe, Balfour, Fothergill, Hayden. *Diseases of the Lungs:* Walshe, D. Powell. *Diseases of the Kidney:* Roberts, Dickinson, Stewart, Johnson, and Beale. *Diseases of the Liver:* Murchison, Habershon. This long list by no means includes all the works which may be selected from, but it will be seen that we do not wish to imply that the student should have to consult one-fourth even of the above. It will be necessary for him to procure one text-book, and the following brief hints may guide him in his selection:—Each has its own peculiarities. That of Dr. Tanner, edited by Dr. Broadbent, has been longest in the field, and is fully sufficient for most purposes; it is eminently practical. The handbook of Dr. T. F. Roberts is, however, perhaps the most useful, and abounds in information supplied in a thoroughly systematic manner, although, from the very extensive range travelled over, the subject is necessarily condensed, and the book, therefore, no light reading. The work of Dr. Bristowe is more original, and is valuable especially in its pathological portions, and in the admirable account given of diseases of the nervous system. Dr. Aitken's "Outlines" are also good. But for a work which is both pleasant in the reading and valuable for its suggestiveness, the text-book of Professor Niemeyer takes the front rank. Certainly no candidate for the higher examinations should fail to read this book, and to carefully study it, for although in some sections it hardly comes up to the standard of some English authorities, yet, as a whole, there is no work like it. Dr. Flint's work has obtained a wide and deserved reputation, not only in America but also in this country. Nor should Dr. Watson's famous book on the "Principles and Practice of Physic" be omitted, for many an hour may be passed both profitably and with pleasure in the perusal of these classical lectures. Those who intend taking high degrees, such as the M.D., should read much of the "System of Medicine" edited by Dr. Reynolds, and the time would not be wasted in the perusal also of several of Trousseau's admirable lectures on Clinical Medicine, translated by the Sydenham Society. Such candidates also would do well to read the monographs of Dr. Murchison on Diseases of the Liver, or those on Diseases of the Kidney by Drs. W. Roberts, Grainger Stewart, or Dickinson; and also to consult Dr. Walshe's works on Diseases of the Lungs and Diseases of the Heart, or the lectures of Dr. Balfour on the last-named subject. On Continued Fevers, there is no work comparable to Dr. Murchison's treatise. On Diseases of the Nervous System there are the larger works of Ross, Rosenthal, and Hammond; but the lectures of Dr. Wilks, and those of Charcot, which have been translated by the Sydenham Society, may profitably be read. Dr. Bastian's lectures on Brain Diseases, Dr. Gowers' lectures on Diseases of the Spinal Cord, and Dr. Buzzard's clinical lectures are all admirable as examples of clinical exposition in this attractive region. Lastly, we can recommend the student to consult on any or all of the subjects connected with medicine the Dictionary published under the editorship of Dr. Quain; whilst no sketch of medical literature would be complete without mention of the great work of our time—Ziemssen's *Cyclopædia*—for the translation of which we are indebted to American enterprise, and a copy of which is sure to be found in every school library.

Clinical Medicine: Da Costa, Finlayson, Fen-

wick, Tanner, Gee, Barclay, Warner. *Urine Analysis*: Legg, Tyson. *Ophthalmoscopy*: Browne, Jackson, Gowers, Clifford Allbutt. The first-named, that of Dr. Da Costa, is of the highest class. The handbook edited by Dr. Finlayson is very complete of its kind; Dr. Fenwick's work is smaller, but has been much in use; whilst the subject of "physical signs" in chest disease is admirably treated of in Dr. Gee's little manual on Auscultation and Percussion. To the clinical ward clerk the guide compiled by Dr. F. Warner will be found of considerable utility. As aids in the analysis of urine, Dr. Legg's and Dr. Tyson's works are excellent. We have added four works on Ophthalmology; the first is a guide to the use of the ophthalmoscope, which the beginner will find of great service; but the senior student will be repaid by studying the excellent work, which includes an atlas, by Dr. Gowers, or the book by Dr. Clifford Allbutt on the same subject. For reference, Liebreich's plates, or preferably those of Jaeger, edited by De Wecker, may be consulted.

Pathology.—Green, Payne, Coats, Ziegler, Wilks and Moxon, Rindfleisch, Cornil and Ranvier, Rokitsansky, Billroth, Paget. The most popular text book for some years past has been Dr. Green's small work, but there has long been a need felt for a more comprehensive treatise on a subject which is more than ever receiving attention. During the past year two excellent works have appeared which go far to supply this want. The one is the "Manual of Pathology," by Dr. Coats, of Glasgow, which is a work of high merit, and is sure to be widely read. The other is the equally attractive work of Ziegler, the first part of which only has yet appeared in an English dress in the careful translation of Dr. Macalister. A second part will soon be published, but the work has not yet been completed in the original. Ziegler's book is as notable for its illustrations as for the clearness and conciseness of its text. Dr. Payne's edition of Jones and Sieveking's Pathological Anatomy, and the text book of Wilks and Moxon are valuable, the latter being especially distinguished for the descriptions of diseased organs. In Pathological Histology, besides the works above mentioned, the advanced student will find no better guides than Cornil and Ranvier's work, the second edition of which has partly appeared in English in Mrs. Hart's translation, an American copy of the first edition being also available. Then there is the work of Rindfleisch, translated by Dr. Baxter. In Surgical Pathology Mr. Pepper has written a book for Cassell's series which will doubtless be of great use to the student; and Mr. Walsham's "Manual," comprising an analysis of the contents of St. Bartholomew's Hospital Museum, is a careful compilation and guide. Billroth's "Surgical Pathology" is well worthy of study; whilst Sir James Paget's well-known lectures abound in suggestive matter.

Surgery.—Druitt, Bryant, Holmes; Erichsen, Spence, Pirrie, Syme, Gross, Agnew, Holmes's and Hulke's System, Gant. *Practical*: Hill, Heath, Stimson, Stephen Smith, Bell and Maunder; Fergusson. *Surgical Anatomy*: Bellamy, Chiene, Treves. The two text books by Mr. Bryant and Mr. Holmes respectively, are perhaps now the most widely read. Druitt's "Vade Mecum" is now less sought after; still, by some it may be preferred to either Bryant or Holmes. Of larger works Erichsen's "Science and Art of Surgery," or Gross's Surgery, need only to be mentioned; their merits are well and widely known. And the same may be said of Holmes's System of Surgery, a new and cheaper edition of which, under the joint editorship of Mr. Holmes and Mr. Hulke, has recently appeared. Mr. Gant's work is compendious. Prac-

tical Surgery has been treated by the late Sir. W. Fergusson, Mr. Spence, Dr. Pirrie, and Mr. Syme, in books which have obtained a deserved repute. The works of Bell, Maunder, and Stimson on Operative Surgery, and Mr. Heath's Atlas, are all excellent. Mr. Hill's book on Bandaging and Mr. Heath's two small works on Minor Surgery and on Surgical Diagnosis are of great use to the student in his career as dresser or house-surgeon. Mr. Keetley's Index of Surgery is a work which contains much information within moderate compass. In Surgical Anatomy we are promised a small textbook in Cassell's series, by Mr. F. Treves; and on the same subject there are also the excellent works of Prof. Chiene and Mr. Bellamy.

Midwifery.—Swayne, Meadows, Lloyd Roberts; Playfair, Leishman, Barnes, Clay, Lusk. *Diseases of Women*: Lombe Atthill, Galabin, Barnes, Graily Hewitt, Thomas. In the department of Midwifery the best works are those of Dr. Playfair, Leishman, Lusk, and Dr. Robert Barnes' or Mr. Clay's works on "Obstetric Operations." With these the student preparing for University degrees would be well armed; whilst for emergencies Dr. Swayne's "Obstetric Aphorisms for Students" is excellent, and may be used in conjunction with the lectures attended by the student. In *Gynaecology* the small book of Dr. Lombe Atthill is deservedly popular. Of like scope is the handbook by Dr. Galabin. Of rather wider range is Dr. Edis' work on "Diseases of Women;" and still more extensive information may be found in the larger works of Drs. Barnes, Graily Hewitt, and Thomas.

Dermatology.—Liveing's Diagnosis, Fox's Epitome, Duhring, Malcolm Morris; Tilbury Fox, Neumann (Pillar's translation). *Atlases*: Tilbury Fox, Duhring. The student will find ample information within a small compass in the first-named works. Duhring's book is not so well known in this country as it deserves to be, and Neumann's is especially rich in cutaneous pathology.

Diseases of the Eye.—Lawson, Nettleship, Macnamara, Soelberg Wells. The most useful for the student are the two first named.

Diseases of the Ear.—Allen, Dalby, Keene, Field, Hinton, Woakes.

Dental Anatomy and Surgery.—O. Tomes, J. Tomes, Salter, Harris, Sewell.

Medical Electricity.—De Watteville, Reynolds, Poore, Bennett.

We need but enumerate the authors in the above subjects; and we have only to add one subject which is still included in the University of London curriculum for candidates for the M.D. degree:

Logic and Moral Philosophy.—Bain and Jevons are the authors most generally read; but those who can make the acquaintance of Mill, Lewes, and Spencer will not regret it.

Lectures

ON THE

RELATIONS OF THE TUBERCLE BACILLUS TO PHTHISIS.

By C. THEODORE WILLIAMS, M.A., M.D.,

Fellow of the Royal College of Physicians; Physician to the Hospital for Consumption, Brompton.

LECTURE II.

ITS INFLUENCE ON THE CLINICAL HISTORY AND TREATMENT.

GENTLEMEN—We now come to the clinical aspect of the question, and it would be best to approach the subject, first, by the light of the evidence of physical signs, and, secondly, by that of the con-

stitutional and local symptoms, such as pyrexia, wasting, cough, expectoration, and general aspect. Do we find bacilli in the sputum of patients in the stage of early consolidation, where the physical signs are slight and limited to a very small region—for instance, the supra-clavicular or the supra-scapular? My experience would answer in the affirmative, provided there is any expectoration to examine, which is often a difficulty. Objection will be at once raised by sceptics in physical signs, who will assert that in no case can we be quite certain of the absence of excavation. While admitting that many cavities are overlooked, and that small ones, especially when deep-seated, are very difficult to detect, I maintain that a case like the subjoined does not admit of much doubt.

CASE 2.—Edith C—, aged seventeen, milliner and dressmaker, admitted on Dec. 30th, 1882. No family predisposition. Has had pain under the right clavicle for three months, which kept her in bed and out of work for one week. She states that she has no cough, but that some expectoration follows a tickling in the throat. She has not lost flesh or had night sweats. At present her breath is not short. Tongue clean; bowels and catamenia regular; temperature and pulse normal; weight 8 st. 6½ lb. Dr. Percy Kidd, who admitted her in my absence, found weak respiration with prolonged expiration in the first interspace and above the scapula on the right side.—Feb. 22nd, 1883: has gained 6 lb. The expectoration is so scanty that it is difficult to obtain any; it has been examined three times for bacilli; on the first two occasions none were found, but on the third a few were detected. Physical signs: Tubular sounds audible in the first and second interspaces.—March 15th: Has improved in strength, and a little in weight, being now 8 st. 13½ lb.; bacilli present in the expectoration, but very scanty. Physical signs: Tubular sounds in first and second interspaces, with occasional crepitation in the first interspace on coughing. Temperature 98.4° F. (A specimen of this patient's sputum now under the microscope shows from five to ten bacilli in the field.)

In the foregoing case the signs may be said to have developed while under observation, the crepitation, be it noted, appearing at a later date than the prolonged expiration or tubular sound. The bacilli could only have reached a small number of the alveoli, and detection was consequently very difficult. The extension of the disease is generally accompanied by either an increase in the bacilli, or, if they had previously disappeared from the sputum, by their reappearance. It is not always easy to find cases of this sort without the presence of a cavity, which, small though it be, would by some observers be considered the source of all the bacilli present. I think, however, that in the subjoined instance the fine crepitation indicated for the most part fresh tuberculization, especially as on the right side its diminution was unaccompanied by cavernous sounds, and on the left side the tubular sound which followed was associated with increase of dullness.

CASE 3.—Jessie B—, aged thirty-one, servant, admitted on Jan. 31st, 1883. Her mother died of phthisis at the age of forty-six, one brother at twenty, one sister, at twenty-nine, and another at twenty. She had inflammation of the lungs following measles, but completely recovered. Cough came on eleven months ago, and has persisted, accompanied by abundant expectoration, occasionally streaked with blood. She has had night sweats, and has wasted considerably. At present she complains of pain in the left chest; cough is severe; expectoration scanty; breath short on exertion; no night sweats; appetite good; tongue

clean; temperature 98.8°; weight 9 st. 8½ lb. Physical signs: Slight flattening with crepitation from the clavicle to the third rib on both sides; some tubular sound on the left over the same area. Crepitation audible above both scapulae.—Feb. 8th: Cough improved; expectoration decreased; bacilli numerous.—March 1st: Cough about the same; expectoration partly grey, partly purulent; crepitation less on both sides of the chest.—15th: Improving; has gained 3 lb.; expectoration 1 oz., with bacilli in fair numbers. Physical signs: On the right side, crepitation diminished front and back. On the left side, dullness to the third rib, with tubular sound; crepitation less.—April 9th: Cough less; expectoration diminished; bacilli absent; weight 9 st. 13½ lb.; physical signs as before.

In this case the numbers of the bacilli corresponded pretty exactly with the activity of the tuberculization, and when the disease became quiescent, they disappeared from the sputum. This instance would come under the category of Mr. Cheyne, where the bacilli enter the lungs and not the body; though here the soil was well prepared by family predisposition. The general health was excellent, and there was fair hope of the disease remaining localized. The following case is somewhat similar, and the disappearance of the bacilli accompanied the subsidence of the physical signs.

CASE 4.—Frank R—, aged twenty-six, footman, admitted on March 19th, 1883. His mother died of some disease of the lung, and a brother and a sister are asthmatic. After exposure late one night, a year ago, when out with the carriage, cough and expectoration came on, and have continued ever since. Night sweats followed and persisted for six months. He lost flesh at first, but has regained it lately. His breath has been short on exertion for some time. Has never had hæmoptysis. The cough at first was very severe, and ended in vomiting. The expectoration has been white and frothy, but lately has become somewhat opaque. At present his appetite is fair; tongue furred; some dyspepsia after food; bowels confined; temperature 98.4°; pulse 90; urine normal. Physical signs: On the left side slight dullness with fine crepitation from the clavicle to the third rib; posteriorly, scattered crepitation audible over the upper half.—30th: Sputum examined, and found to contain twenty bacilli in the field, and these in a state of division.—April 9th: Cough more troublesome; expectoration increased; appetite bad. The patient states that he does not feel so well.—11th: Sixty bacilli in the field, of greatly varying lengths.—16th: Cough and expectoration somewhat less; complains of pain in the left chest. Physical signs: On the left side crepitation somewhat more abundant in the posterior region.—17th: About thirty bacilli in the field, still greatly varying in length.—23rd: Physical signs about the same. No cavity can be detected. Cough and expectoration are moderate, and the patient is gaining weight.—May 7th: The patient is not so well, and coughs more. Crepitation has increased, and is audible as low as the fifth rib on the left side. Since admission the temperature has risen to 100°, and the morning records have been subnormal.

The above seems to be a case of advancing tuberculization of one lung; and the interesting feature is that the spread of the crepitation downwards was preceded by a division of the bacilli noted on March 30th, and their being detected in greater abundance in the field on April 11th, when they were still found to vary considerably in length, as if there was a prospect of further multiplication and consequent spread of disease.

CASE 5.—Arthur B—, draper's clerk, aged

thirty, admitted on March 19th, 1883. For eight years he has been subject to winter cough, and for four years cough has been continuous, and during the last two years he has complained of shortness of breath, which increased so much at Christmas, 1882, and was accompanied by such debility that he had to give up work. Two years ago he had slight hæmoptysis, and night sweats have occasionally appeared. He has during this time lost more than a stone in weight. At present he complains principally of shortness of breath, especially on exertion, cough severe night and morning; expectoration yellow, but sometimes frothy. Physical signs: Slight dulness with crepitation from clavicle to the lower edge of fourth rib on the right side. Sonorous rhonchus audible at the base posteriorly.—30th: The sputum contains a few bacilli.—April 2nd: Breathing rather easier, but patient weak and languid. Cough less, expectoration scanty. Physical signs on right side the same as before, on left side some wheezing and rhonchus are audible.—9th: Cough and expectoration less. Sputum contains a fair number of bacilli, forty in the field. Some single ones, but many in faggot groups of two three, and four. The bacilli vary in appearance. Some are simple rods without beadings, and others again show the beading well.—16th: Breath still rather short; expectoration deeply stained with blood during the last few days. Fine crepitation is audible in the interscapular region on the left side.—17th. Forty bacilli in the field, still varying in size.—23rd: Fine crepitation is also audible at the right posterior base.—May 7th: Cough rather worse, expectoration same in quantity but tinged with blood. Temperature rises at night to 100°. Physical signs the same.—June 4th: Expectoration has diminished. Temperature high at night. Physical signs the same on the right side; on the left there is crepitation at the extreme base anteriorly, and in the scapular and interscapular regions posteriorly. No cavernous sounds can be detected anywhere. Examination of the sputum shows abundant bacilli, fifty in the field, and with well-marked beadings.

In the foregoing case the disease undoubtedly progressed, the physical signs indicating increase of tuberculization in the same lung, and also extension to the opposite one. No cavity was detected, but with a history of so long standing we cannot be sure of the absence of such. The main feature of the case was progressive tuberculization, and we may fairly connect with this the large number of bacilli, the increase between March 30th and April 9th, and the well-marked bundles which are so characteristic of active changes.

The above cases might be easily multiplied; but they will at any rate suffice to demonstrate that the bacilli are present in the sputum when only consolidation can be detected, and we may conclude that their number corresponds to the number of alveoli in which tubercular changes are proceeding. Moreover, where a small and quiescent cavity is known to exist in one lung and the physical signs indicate an extensive spread of tuberculization in the opposite lung, without any defined spots of coarse crepitation or gurgled to signify that fresh excavation is taking place—if under these circumstances we find an increase in the number of bacilli in the sputum, we are fully justified in attributing such increase to the fresh tuberculization, and not to the old quiescent cavity.

The relation of the bacilli to the process of excavation appears to be very intimate, and their numbers increase largely while the latter is proceeding. Even when there is apparently no cavity extension they are found in the sputum, and continue to be so as long as there is any discharge

from the cavity. Cases 6 and 7 are good instances of their relation to caseation and softening.

CASE 6.—William S—, aged twenty-six, laborer, was admitted February 2nd, 1883. No family predisposition. Has been subject to winter cough for some years. After a succession of wettings last Easter, cough with expectoration increased, and his breath became shorter. Six weeks ago there was slight hæmoptysis, and he has had night sweats for three months, and has been losing flesh since Easter, having wasted to the extent of two stone. At present cough troublesome, expectoration muco-purulent and aerated; breath short, night sweats severe. Tongue has an irritable look, appetite very poor; the patient suffers from dyspepsia. Pulse rapid, temperature 100.6°. Physical signs: Right side, crepitation to the third rib, with some tubular sounds. Left side, crepitation to the fourth rib; crepitation audible above both scapulae.—12th: Has had diarrhoea for two days; three motions a day; is sweating less. Temperature has ranged from 97° to 99° in the morning, and from 100° to 103° in the afternoon.—19th: Diarrhoea ceased; breath short on exertion; bacilli in sputum abundant. The evening temperature has ranged from 100° to 102°.—26th: Has complained of pain in the right side for the last few days, and friction is audible over the lower front. The pain has been relieved by strapping; cough very troublesome; bowels rather relaxed. Physical signs: Cavernous sounds audible on the left side over limited areas in the first, third, and fourth interspaces, where there is some flattening and retraction of the spaces on inspiration. The heart is apparently uncovered by lung. On the right side the crepitation remains the same. Bacilli scanty.—March 5th: Cough and expectoration less; appetite improving. Physical signs the same. Bacilli in sputum scanty. The temperature has fallen, ranging from 98° to 99.8°.—19th: Symptoms have become worse; temperature rises to about 101° every night. Cough worse; the patient is unable to lie long on one side. Physical signs: On the left side cavernous sounds more marked, with less crepitation. On the right side crepitation greatly diminished, with doubtful cavernous sounds under the clavicle.—April 2nd: Cough more troublesome, accompanied by retching; expectoration increased; night temperature ranges from 101° to 102°; night sweats troublesome; on the left side physical signs as above; on the right side crepitation has extended to the fifth rib; bacilli few and dividing.—9th: Cough about the same; expectoration muco-purulent, with patches of pigmentation; temperature at night 100° to 102°; bacilli abundant, sixty in the field, either single or in groups of three; they have well-marked beadings, and apparently are in a state of division.—16th: Symptoms about the same; on the right side crepitation is increased front and back; cavernous sounds are audible on the left side to the fourth rib. Evening temperature 101°.—May 8th: Patient worse; has wasted greatly; more crepitation is heard on the right side front and back; cavernous sounds detected in both lungs.

The increase of the bacilli seems in this case to have preceded the detection of the excavation by a considerable period, a week elapsing between the noting of "abundant bacilli" and the cavernous sounds being heard in the left lung. On the right side the physical signs came before the increase of the bacilli, but later on the lung excavation changes were accompanied by great activity of the bacilli. Their numbers increased, they showed well-marked beadings or spores, and arranged themselves in the little faggot bundles which generally indicate, or usher in, fresh tubercular outbreaks. The appearances of division men-

tioned in this case are when the bacilli show greatly varying lengths.

CASE 7.—Wm. B., a bricklayer, aged forty-six, was admitted on Feb. 5th, 1883. His mother and two brothers and sisters asthmatic. History: The patient has had cough for two winters, which has become persistent since last March, and is accompanied by expectoration. He has had shortness of breath for two or three years, which has lately increased. For twelve months he has lost flesh to the extent of a stone. He has never had hæmoptysis or night sweats. Cough troublesome; breath short on exertion; tongue slightly furred. Temperature and pulse normal. Expectoration frothy, with some yellow streaks, and contains abundant bacilli. Weight 8 st. 2½ lb. Physical signs: Chest hyper-resonant; wheezing and sonorous rhonchus audible over the whole lungs; slight dullness in the first intercostal space on the left side.—19th: Cough about the same; physical signs the same; bacilli in sputum still abundant.—26th: Cough more troublesome; expectoration abundant; some crepitation in the left side in the fourth interspace on coughing; wheezing and rhonchus audible everywhere; bacilli abundant and dividing.—March 5th: Has suffered much from cough and wheezing, but now the former is easier and the expectoration much less; bacilli few in number.—April 2nd: The breathing has improved during the last few days. The expectoration is very abundant, yellow, and comes up easily. Pulse 104; temperature 99° 2'; respiration 22. Bacilli very few in number. Physical signs: Less rhonchus over the entire lungs, and now chiefly confined to the left side. Doubtful cavernous sounds audible above the left clavicle on coughing.—9th: Cough less; breathing better; expectoration diminished; appetite good; distinct cavernous sounds above the left clavicle; bacilli few, four or five in the field, with an occasional group of three.

This case is interesting with reference to its diagnosis, as well as regards the progress of the cavity formation. There was a strong family history of asthma, and dyspnoea appears to have accompanied, if it did not precede, cough in the history. Had it not been for the wasting and slight dullness in the first interspace on the left side we would hardly have expected phthisis, especially in a man of forty-six, and while the abundant expectoration made us suspect excavation, the examination of it settled all doubt, though it was not till the wheezing and rhonchus had entirely cleared up, that we were able to hear the cavernous sounds. Possibly had we examined for lung-tissue this might have been made out earlier. The reduction in the number of bacilli when excavation had finished was as marked as in Case 6. The following case is an example of excavation taking place in phthisical consolidation following pleurisy, the bacilli being present during the period of lung destruction.

CASE 8.—Albert B., a laborer, admitted Jan. 19th, 1883, aged nineteen. No consumption in the family. He had pleurisy at fourteen, and has since had three attacks, the last being in March, 1880. Cough constant since the pleurisy, and worse in winter; it has been increasing lately. Expectoration has diminished, but is thick, greenish-yellow, sometimes frothy. He had hæmoptysis to the extent of twelve to fourteen ounces two years ago. Has had occasional night sweats, but none lately, and has lost flesh since 1880. At present he complains of pain in the right chest, palpitation, shortness of breath, and cough. Physical signs, dullness in the lower third of left chest anteriorly, and the upper half posteriorly. Crepitation on cough, audible in the first interspace. Weight

10 st., 7½ lb.—Feb. 5th: Expectoration has been slightly streaked these last three days; cough less; bacilli abundant in the sputum.—19th: Expectoration again streaked, but contained no bacilli.—March 12th: Gaining weight rapidly and improving; no bacilli in sputum.—20th: Improving; has gained 9 lb. in weight; cough slight; expectoration yellow. Physical signs: Left side, tubular sound below the clavicle, slight dullness in the first two interspaces, slight crepitation on cough in the second interspace; cavernous sounds heard posteriorly above the scapula; sputum contains bacilli.—11th: Has improved and gained nearly a stone during his stay in the hospital. Cough moderate; expectoration slight; breath short on exertion; bacilli scanty, about six in the field of the microscope.

The subjoined is a good instance of the relation of the bacilli to laryngeal phthisis with advancing tubercularization.

CASE 9.—Annie S., aged twenty-three, asylum attendant, admitted on March 16th, 1883. Her mother suffered from chest affection. Cough came on in March, 1882; it diminished in the summer, but increased again last October. At first there was no expectoration, but latterly it has amounted to half an ounce a day, and occasionally it has contained a few streaks of blood. She suffered from pain in the left chest and shortness of breath on exertion. She lost her voice twelve months ago, and has not regained it. During the last fortnight she has had diarrhoea. Has not lost much flesh. Evening temperature 99° to 100° F. The symptoms have continued up to the present time. Physical signs: Left chest—dullness, slight flattening, and rather coarse crepitation from the clavicle to the lower border of the third rib; dullness and crepitation over the upper fourth posteriorly. Weight 8 st. 1½ lb. Dr. Percy Kidd examined the larynx, and found an old ulcer with ragged edges on the posterior wall, with cords reddened, and showing incomplete adduction; he pronounced it to be a case of laryngeal phthisis.—March 30th: Cough more troublesome; expectoration slight. Complaints of pain in the left axilla. Bacilli very abundant in the sputum, and arranged in bundles.—April 26th: Cough still troublesome; expectoration decreased; larynx tender. The evening temperature has ranged from 99° to 101° F. Crepitation audible on coughing in the first interspace on the right side, and to the fifth interspace on the left side. The bacilli were few in number fourteen days ago; they have now become abundant, numbering thirty to forty in the field. Voice about the same.—May 1st: Has had diarrhoea during the last two days; four motions a day. The temperature rose last night to 103° F.—June 10th: The patient has been more or less feverish during the last five weeks, and often confined to bed. Cough less; voice the same. She has lost flesh steadily, and now only weighs 7 st. 6 lb., a loss of 9 lb. Pulse 112; evening temperature 101° F. Physical signs: Right side—slight dullness in the first interspace. Left side—dullness as before; crepitation greatly diminished, but still audible to the fifth rib, and posteriorly over the upper half. Dr. Kidd examined the larynx, and found it in much the same state as on admission. The ulceration had not extended, and the adduction of the vocal cords was still imperfect. The sputum contained from ten to fifteen bacilli in the field.

In this case the advance of the disease took place in the lungs, and not in the larynx, being ushered in by an increase in the number of bacilli. With the diminution of crepitation the number of bacilli in the sputum sank.

In cases of quiescent cavity we find bacilli

present in numbers corresponding chiefly to the amount of discharge, which, as a rule, is very small. When the cavity contracts this may be reduced still more, and in many instances of this kind they cease to appear in the sputum, not because they no longer exist in the lungs, but rather because the communication between the cavity and the bronchus being blocked by the increasing lung contraction, the bacilli cannot escape with the sputum, which under these circumstances is purely bronchial; at any rate this is the case with the sputum ejected from that lung. I had a good instance of this in the case mentioned in the statistics of bacilli. Many cases of contracting cavity, where there is considerable dislocation of the adjoining organs; and where the cavernous sounds are barely audible, nevertheless show bacilli in the sputum, because the bronchus leading to the cavity remains patent; but if these are few in number and there is strong evidence of fibrosis, their presence need not much modify the prognosis of the case; on the other hand, when a cavity opens into the pleura and pneumothorax results, the number of bacilli increases considerably, as I noted in a well-marked case of acute phthisis ending in pneumothorax under my care last winter.

We will now consider the relation of the tubercle bacilli to the general symptoms of phthisis. The perusal of the above cases will show that they do not materially affect the gain or loss of flesh. As regards pyrexia, the question is more difficult to determine, but it may be safely affirmed that they are present, and in fair abundance, in non-pyrexial phthisis. When pyrexia accompanies tubercularization and exudation they certainly increase largely, but this may depend on the local processes, and not on the general irritation.

In the case of a girl, aged seventeen, with a cavity at one apex and some tubercularization taking place at the other, the temperature ranged between 100° and 103·6° F. for fourteen days, and it was not until four specimens of the sputum had been tested that we succeeded in finding bacilli, and then only in small numbers. In another female patient, aged fourteen, with a cavity in each lung, where the temperature course occasionally ran high, bacilli were found in the sputum, but in small numbers. A third case, also one of double cavity with pyrexia, showed a temperature chart between 100° and 103·6° F. for sixteen days, yet bacilli were only detected in the sputum in small numbers. On the other hand, some cases in which the bacilli have been particularly abundant have shown no pyrexia, and the explanation appears to me to lie—first, in the fact that both tubercularization and excavation may take place without pyrexia; secondly, that the examination of the sputum only teaches us what is going on in the lungs, which doubtless in cases of active pulmonary changes means a good deal, but when the blood is poisoned and the system generally becomes infected, we must not expect the sputum alone to give explanations, which should be sought in other secretions. At present our testings of the blood have failed, but I have no doubt that this will not always be so.

Prognosis.—Much stress has been laid by writers on the value of the bacillus tuberculosis in prognosis, and the cases I have given demonstrate this strongly, the unfavorable elements being, first—the rapid increase of bacilli, and, second—their arranging themselves into groups, both of these phenomena indicating activity or extension of the disease.

Infection.—The detection of the organism special to phthisis in the breath and sputum of consumptive patients naturally would lead us to conclude

that it must be infectious, especially when it is remembered that owing to a large portion of the population being phthisical it is probable that in many of the houses and streets the air is impregnated with lung exhalations and dried sputum.² Still cases of infection are very rare. The evidence of this large hospital, now established thirty-seven years, has been published by me elsewhere,³ and shows that among its resident staff of medical officers, clinical assistants, matrons, nurses, and servants, the contraction of the disease by infection is practically unknown, for among some hundreds of residents only two instances of the disease having commenced during stay in the hospital can be cited, and in each of these there were special circumstances. The non-resident staff also appear exempt, except the dispensers, who have little or nothing to do with the patients, but who nevertheless, owing probably to bad ventilation of the old dispensary, have had some cases among them. There have been times when, owing to defects arising in the ventilation, the air of the hospital has become undoubtedly impure, and erysipelas and sore-throat have appeared in the wards; but although we have carefully watched for instances of infection among the non-consumptive cases under these circumstances, we have never found them. This, considering that the bacilli must accumulate at such periods, is worth noting. When, however, I am asked if phthisis is communicable I answer, Yes; I believe it can be communicated, though it rarely is, under certain conditions, which are as follows:—1. By constant inhalation of the breath of a patient suffering from acute tubercular disease, undiluted with the proper quantity of fresh air. To produce this result the sick and healthy must sleep in the same room, and probably occupy the same bed, facing each other; the ventilation must be very bad, and the healthy person must be weakened by anxiety and nursing. The commonest examples of this form of infection are mother and daughter, or two sisters sleeping together, and the healthy one sickening of consumption after nursing the other. Here, again, we generally have a certain amount of family predisposition to take into account, as in the case of mother and daughter; if the daughter's disease comes on after the mother's, we are apt to conclude at once that it is hereditary, and in the case of the mother's disease following the daughter's it is said that the predisposition to phthisis already existed in the mother, that she transmitted it to her daughter, and that it developed late in herself. I am inclined to think that we are assigning too much to heredity in some of these cases. Taking these intimate relations of life between the healthy and sick into consideration, we must not forget the many negatives, where under these very conditions phthisis is *not* contracted, and we must compare them with the few positives, where it is so contracted. 2. From husband to wife, or vice versa. This may occur (1) through coition, or (2) through inhalation of the breath. Dr. Hermann Weber's cases are the principal evidence of the first form, these being for the most part instances of wives being infected by husbands, infection only taking place after pregnancy, and the disease then assuming an acute form. Dr. Weber pointed out how much more liable the wife was to such infection than the husband, who was the

² An interesting confirmation of this is to be found in MM. Malassez and Vignal's experiments (Brit. Med. Jour., August 18th, 1883). The zoögleic masses which these authors describe, and apparently connect with the tubercle in which no bacillus is found, are probably the same as the blue micrococci of Heneage Gibbs, which have often been detected in phthisical sputum, accompanying the bacilli.

³ British Medical Journal, Sept. 30th, 1882.

subject of attack in only one of his cases. Here, again, we cannot help reflecting on the numerous opportunities of such contagion, and of the rarity of its occurrence. I have known a few instances of the first form of infection, and as regards the second (that between husband and wife) I have a good instance in a widow, in the Derby ward at present, where infection took place probably through the inhalation of breath, and not through pregnancy, as the patient recovered thoroughly from her confinement.

CASE 10.—Harriet P., aged twenty-six, a widow, formerly lady's-maid, admitted April 30th, 1883, with the following history. Father alive, aged sixty-three, healthy; mother aged fifty-four, healthy; paternal grandfather died at the age of eighty-two; maternal grandmother upwards of seventy years of age before death. Has three brothers and four sisters younger than herself, and all healthy. She was apprenticed to dress-making from the age of sixteen to nineteen, lady's-maid from nineteen to twenty-two, and when she married, in 1879, was in excellent health. Her husband was attacked with consumption soon after marriage, and died in August, 1881. About two years after her marriage she was confined, and recovered perfectly, the child (a girl) being somewhat sickly, with a slight cough. The patient nursed her husband throughout his illness of two years duration, living at the time in small contracted rooms very deficient in ventilation, the bedroom having no fireplace, and being only ventilated through the sitting-room, and being quite unfit for habitation. The husband's disease was of an acute character, with well-marked pyrexia, and in addition to large cavities forming in the lungs, causing profuse expectoration, there was tuberculous ulceration of the intestines, giving rise to obstinate diarrhoea. The patient had a slight cough at the time of her husband's death, which disappeared shortly after. Her chest was examined by me at this time and found free from disease. She remained in fair health for six months, when the cough returned with a small quantity of expectoration, which about last Christmas became yellowish, and increased in quantity till it reached two ounces daily. At that time night-sweats came on and she lost flesh (about 8 lb.) She has had no hæmoptysis. On March 22nd, 1883, she was examined by me, and I found on the left side dullness and coarse crepitation from the clavicle to the fourth rib and above the scapula, and crepitation in the first interspace on the right side. On April 16th I examined her again, and found the symptoms worse, and that the crepitation on the left side had extended over the upper half of the lung. On admission to the hospital, April 30th, her cough was slight and the expectoration nummular (half an ounce); breath short on exertion; night-sweats slight; bowels regular; appetite fair; catamenia too frequent. Pulse 100; evening temperature 100.4° F. Weight 7st. 4lb. Physical signs: Right side—dullness: crepitation from clavicle to third rib with click sounds above the clavicle; crepitation over the upper third posteriorly with tubular sound above the scapula. Left side—dullness from clavicle to third rib; cavernous sounds audible in the first two interspaces close to the sternum; posteriorly dullness over the upper half with loud cavernous sounds above the scapula. Since admission the temperature has been somewhat high. Bacilli have been abundantly detected in the sputum.

It is seldom that we come across a history so free from family predisposition to phthisis as this one, and the only drawback to accepting the case as one of infection is the period which elapsed between the death of the husband and the

development of the symptoms. These, however, came on so rapidly, both lungs appearing to be simultaneously attacked, that we must conclude the cause of the disease was something in the system, and not the result of cold. It is possible that the bacilli can lie dormant for a while, and multiply and become active after a time; or, on the other hand, they may, for a period, be present in such small numbers as not to give rise to processes which can be detected by physical signs.

A third form of infection is through eating tuberculous meat, or drinking of the milk of diseased women or animals. Several cases of this kind have occurred on the Continent, but they are, happily, little known here. The remarkable cases of bovine tuberculosis in man related by Dr. Creighton⁴ may also be due to this cause.

What measures should be taken to prevent the above forms of infection? 1st. Good ventilation of the rooms inhabited by the healthy and sick, and especially of the bedrooms. 2nd. The consumptive should sleep in a separate bed, if not in a separate room, from the healthy. Where a healthy person shares the same bedroom as a consumptive, the window should be kept open, or a Tobin tube introduced, to ensure abundant fresh air in addition to the ordinary chimney. Where, for unavoidable reasons, the healthy person occupies the same bed as a consumptive, care must be taken not to inhale the breath of the latter. 3rd. The sputum should be frequently removed and disinfected, or, as perhaps there are now doubts as to the efficacy of disinfectants, it had better be burnt. The sputum should be received into a covered cup or spittoon, which only allows of a very limited evaporating surface, and this should contain a strong disinfectant, such as terebene or chlorate of lime, and it should be emptied at least twice a day; and in this way danger of infection from this source may be prevented.

Treatment.—And now comes the question, How are we to combat these bacilli? Shall we apply medicaments directly to the pulmonary mucous membrane? or shall we depend on strengthening the constitutional powers to resist the attack, or shall we try both methods? The treatment of phthisis by vapors or inhalations is very old, and has never been very successful. The form most in fashion at present is that of an ori-nasal respirator, containing a few drops of carbolic acid, creasote, thymol, eucalyptol, with or without some sedative to prevent irritation, a common adjunct being spirits of chloroform. The shapes of the respirators vary greatly, from the simple perforated iron oval one of Dr. Roberts, to the more elaborate ori-nasal form of Cushman. They are worn for periods of from one hour to six or seven hours, taking them off occasionally when irksome to the patient. During the last three years I have made trial of every form which seemed to offer any advantage, using in them a great variety of medicaments. I have specially noted their influence on cases where tubercularization was commencing. Sometimes, though rarely, the cough has somewhat lessened, and the patients have felt soothed by their use; but I have never found them to have the slightest effect in diminishing the local disease, or in permanently reducing the cough. I have noted the extension of crepitation from one apex downwards, or its replacement by the signs of excavation, in spite of continued use of this form of treatment, and though I have often perceived a diminution of the crepitation in early cases, I have never been able to connect it with the use of these respirators.

The contrast between the effects of these and

⁴ Bovine Tuberculosis in Man, 1881.

the results of counter-irritation applied to the chest wall overlying the diseased lung is very striking. The cough, which weeks of inhalations have not relieved, is often at once reduced by the production of a good blister on the skin, and the expectoration, which was difficult, is quickly rendered easy by some forms of saline expectorant, especially if combined with a little antimony or ipecacuanha. Another objection to these respirators is that they seriously impede the freedom of respiration, partly by limiting the movements of the jaws, and partly by the obstruction to the exit and entrance of air, which is caused by the wire gauze. They thus more or less muzzle the patient, and prevent that entire of freedom of respiration which is so essential in phthisis. Some experiments made by Dr. Hassall on the validity of various antiseptics when used in respirators, and published in *THE LANCET*, go to show that creasote, carbolic acid, and thymol are scarcely capable of volatilization at the temperature generally used in these appliances, and that the amount inhaled when the respirators are used for one or two hours daily is so small as to be practically useless. Iodine, on the other hand, was easily volatilized; but, on reaching the mucous membrane of the mouth, appears to be converted into an iodide by combination with the saliva, and it is doubtful how much of the pure iodine reaches the respiratory surface, though some probable may. When carbolic acid and iodine are inhaled together, according to Dr. Hassall, a strong chemical action is set up between them, whereby probably the antiseptic properties of both are impaired.

Those practitioners who firmly believe in the antiseptic, or rather germicide, virtues of carbolic acid in phthisis, will do well to consider the statement of Mr. Watson Cheyne, reported in the *Practitioner*, April, 1883, p. 285, Experiment xiv., No. 3, "One part of the fluid containing bacilli was mixed with one part of a 5 per cent. watery solution of carbolic acid; this stood fifteen minutes, and was then injected into the left eye of a rabbit." After forty-three days the animal was killed and found to have tubercular iritis of both eyes, and with a considerable number of minute tubercles in both lungs, one or two of which showed commencing caseation. The liver and spleen also contained tubercle. Microscopic examination showed abundant bacilli in all these organs. Here the influence of the carbolic acid was brought to bear on the bacilli in a far stronger and more intimate way than is practicable for application to the human body, except we are prepared to follow Dr. Fränkel's example and inject it and other antiseptics, directly into the lungs through the chest wall, and the results of this mode of treatment as practiced by him are not very encouraging. In Mr. Cheyne's experiment the carbolic acid seems to have exercised no influence whatever on the bacilli, which continued to prove their vitality by largely multiplying in the inoculated animal, and this shows the great importance of first studying the conditions of life of these low organisms outside of the human body, and then of testing the effects of various antiseptic drugs on them. In this way we may discover substances fatal to the bacillus, and then proceed to devise methods of applying them, so as to reach and attack the enemy in his strongholds of the human body. But this knowledge can only be attained by long and careful investigation and the work of many patient observers.

Another mode of antiseptic treatment is by hot-water or steam inhalations of various kinds, some form of inhaler being used, and the different drugs kept at a temperature suitable to promote their vaporization. In this way we, at any rate, do

get the drug inhaled to a certain extent. The best form of this treatment seems to be jets of steam spray charged by means of capillary tubes with necessary medicaments, such as may be seen in use in the inhalation rooms of the new hospital at Brompton. The patients receive a good deal of the drug into their bronchial tubes and lungs in a short time, owing to the force of the steam current; but the objection lies in the damp and hot atmosphere which it causes and the inexpediency of subjecting the patient for any length of time to such strong measures.

The third method is by diffusing through the air of a chamber medicated vapors. In this way consumptive cases can be kept under the influence of special drugs for long periods. In this method we only imitate some varieties of climate, such as those of the sea coast, of pine woods, and of sulphur springs, or in the neighborhood of volcanoes. Two rooms are set apart for this purpose in the new hospital, and at the present time two of my wards, containing three beds each, are kept specially impregnated with the vapor of iodine and chlorine respectively, and suitable cases are selected for this mode of treatment. Observations are being made, and I purpose trying the effect of various drugs in this way.

In the treatment of consumption no stone must be left unturned where we can see any reasonable prospect from treatment, local or general; and we must not forget that though various kinds of local treatment, including inhalations, have been tried from time immemorial, it is to the general treatment in the form of tonics, cod-liver oil, and hygienic and climatic measures that we owe the prolongation of life and the majority of cases of arrest of the disease, now happily so numerous. These trusty aids must never be omitted; but we may often combine with them antiseptics in the form of arsenic, quinine, etc., which, by entering the pulmonary circulation, may, as has been often proved to be the case, act more effectually on the local disease than when applied direct to the pulmonary mucous membrane. By such constitutional measures we may do much, and, even if the enemy gain a foothold in the fortress, we may, by strengthening the garrison, cause him to be expelled and the breach repaired. The arrest of phthisis has undoubtedly been produced in many cases by the influence of certain climates, and specially by that of the high altitude resorts. We must remember that though the aseptic character of the air of these last is urged as their chief advantage, the bacillus tuberculosis is found in the sputum of phthisical patients at Davos, as in London, showing that the air of these regions is not absolutely fatal to bacillar life.

Clinical Lecture

ON

MEDIASTINAL TUMOURS.

Delivered in the Western Infirmary, Glasgow,

By DR. McCALL ANDERSON,

Professor of Clinical Medicine in the University of Glasgow.

GENTLEMEN—The patient whom I am about to introduce to your notice presented a variety of symptoms of a somewhat unusual character, and his case is one to which attention may naturally be directed in connection with my last lecture on intra-thoracic aneurism, for the disease under which he labored is not unfrequently mistaken for it. He is a blacksmith, aged fifty-one, and was

admitted on Feb. 9th, 1883, complaining of breathlessness and of swelling of the upper extremities. His family history is obscure, but he seems to have had two sisters, both of whom are dead, one of them having died after childbirth; while his father and mother reached the age of sixty-two. About twelve years ago, after exposure to inclement weather, he complained of a burning pain in the right infra-clavicular region, which does not appear to have been very severe, nor aggravated by respiration, and was unaccompanied by other symptoms; it was treated by means of the application of iodine to the chest wall, and disappeared in about a week. With this exception, he enjoyed good health until the beginning of the winter 1881-82, when he caught cold and was much troubled with cough and expectoration. These symptoms never entirely left him, although he was in great measure free from them during the greater part of last summer. He remained fairly well until about four months before admission, when, after an unusually hard day's work, he got a chill and suffered from shivers. He seems to have been feverish during that night, and the next day his cough became very troublesome, and continued so afterwards. From the onset of this last attack shortness of breath was increasingly complained of, until at last he was unable to lie down in bed. Two months before admission his hands and arms became swollen, but no other part of his body; and latterly he rapidly lost flesh, strength, and color.

Let me now recall the results of our examination of this patient on February 16th. He was extremely emaciated, very weak, and anæmic; but he had no trouble with his digestive organs, and his temperature was normal. The urine was very scanty—three to twelve ounces in the twenty-four hours—high colored; specific gravity 1033, and loaded with lithates; but it contained neither tubercasts nor albumen. His cough was troublesome; there were abundant frothy mucous expectoration and orthopnoea, but the pulse respiration ratio was not materially perverted. At the base of the right lung there was some fulness, marked dullness on percussion, feeble distant breath sounds, and diminution of the vocal fremitus and resonance. These symptoms led to the conclusion that there was considerable effusion of fluid in the right pleural cavity, an opinion which was strengthened by the circumstance that the liver was pushed downwards, and that it did not rise and fall with the respiration. But over and above these physical signs there were others which at once aroused our attention: (a) As in many cases of intra-thoracic aneurism the right radial pulse was weaker than the left; whereas in a state of health if there is any difference in the pulses at all the right is rather the stronger of the two, thus showing that there was some obstruction to the free passage of blood to the right upper extremity. (b) There was marked distension of the veins of the head, neck, arms, chest, and abdomen, indicating that there was some impediment to the free return of venous blood to the right side of the heart. (c) As a consequence of this there was œdema of the arms and hands, which was especially marked upon the right side, but there was no trace of it elsewhere.

Further, on examining the front of the chest, we observed flattening in the supra and infra-clavicular regions, so that the clavicle seemed to project considerably, while there was a distinct prominence of the lower portion of the manubrium sterni, although the patient could not say whether this had occurred recently, or was a congenital malformation. Over the whole of this area, and extending about two inches to the left of the middle line, there was very great dullness on percus-

sion—even more intense than over the pleuritic effusion at the base; the vesicular murmur was quite inaudible, but here and there distant tubular breathing was heard. These physical signs, coupled with the three symptoms previously mentioned, led to the suspicion that there was a tumour in the anterior mediastinum, which had encroached upon the right lung, and which was interfering with the free passage of blood to the right upper extremity, and with the return of venous blood to the right side of the heart.

As regards the nature of the tumour, we came to the conclusion that in all probability it was malignant—(1) because this is the most frequent form of mediastinal tumour; (2) because of the age and sex of the patient, such disease being most frequent in males and in persons who have passed middle life; (3) on account of the rapid development of the symptoms; (4) because of the signs of pleuritic effusion, malignant tumours being very apt to excite inflammation within the chest; and (5) because of the great loss of flesh and strength, and the cachectic appearance of the patient.

A good many cases similar to this one have from time to time come under my notice, two or three of which by way of comparison may be mentioned.

On November 11th, 1874, there was admitted an iron moulder, forty-four years of age, who enjoyed good health until twelve months before admission, when a slight cough set in, accompanied in a few weeks by expectoration, which gradually increased in amount, and six months afterwards having caught a severe cold, the cough became violent and the sputa streaked with blood, and after that time he frequently brought up small quantities of blood. About three months prior to admission he began to experience giddiness, oppression, and a sense of suffocation on making violent muscular exertion, especially on stooping, lifting heavy weights, etc., but these symptoms passed off on assuming the erect posture, or after resting awhile. About the same time slight puffiness of the neck was observed, and three weeks before admission, all his symptoms being aggravated, he was obliged to give up work. He never complained of headache, but on stooping or coughing his sight became dim, everything appearing as if in a mist. During his whole illness he occasionally felt a dull aching pain, sometimes of a burning character, shooting through from the right breast to the scapula, which was aggravated by hard work; and latterly on carrying his hand backwards towards his shoulder a pain seized him in front of the upper arm below the shoulder, and prevented him from completing the act. His general health seems to have been above the average, although he took stimulants pretty freely. On examining this patient's chest we observed that at the upper part of the right side anteriorly the movements of respiration were restricted, and that there was marked dullness upon percussion, which was not limited to the area of the lung, but extended across the sternum a little to the left of that bone. Over the whole of the dull space the vesicular murmur was absent, although at the apex tubular breathing and increased voice sound were present. These physical signs, coupled with the following four symptoms, led to the conclusion that there was a tumour in the anterior mediastinum. (1) The pulse at the right wrist was much more feeble than at the left. (2) There was marked dilatation of the superficial veins of the arms, head, neck, and top of the chest, especially on the right side. (3) In addition to the varicosity of the veins there was distinct œdematous swelling of the neck. (4) The breath sounds over the

base of the right lung were very much feebler than on the opposite side.

Some years ago there was admitted under my care in the Royal Infirmary a ship carpenter, aged thirty-two, who gave the following account of himself:—In the month of February, while at sea, he was a good deal exposed, sometimes having his clothes wet for a whole week. About this time he began to cough a little, and the cough never left him, although he improved a good deal under treatment during the summer months. In April shortness of breath set in, with general pain over the front of the chest, shooting through to between the shoulders. At this time, too, the veins of the right side of the neck and chest became distended, and the face gradually assumed a swollen and dusky appearance. During the spring he fainted three times at intervals of some weeks, on each occasion after drinking a cupful of cold water. All the above symptoms had been on the increase for three months preceding his admission. He was unable to lie upon his back, but breathed pretty freely sitting up, or upon either side, especially the left.

On examining his chest we found in the first place that there were the usual physical signs of moderate catarrh of the bronchial tubes, the cough being accompanied with some mucopurulent expectoration, but there were a great many very striking symptoms besides. For we found, on listening to the breathing on the two sides, that it was decidedly louder and more marked upon the right side than upon the left. On inspecting the front of his chest, too, the movements of respiration, particularly at the upper part, were found to be defective. There was marked dullness and increased resistance upon percussion over the whole of the sternum, more marked above, and not only over the sternum, but to a considerable extent on each side of it, especially to the left, in which direction it extended at least two inches. We noticed, likewise, that the upper part of the sternum was somewhat prominent. On placing the hand upon the chest over the dull area, and making the patient speak, the vocal fremitus was observed to be almost entirely absent, and on applying the stethoscope the respiratory sounds could hardly be heard. Then we endeavored to find out the situation of the apex beat, but failed to discover any at all. On applying the stethoscope, however, over the præcordial region, the sounds of the heart were clear and pure. They were most distinct over this region, which led to the supposition that there was no very great dislocation of the heart. On feeling the pulses at the wrists it was noted that the left was weaker than the right. But the most remarkable symptom having reference to the organs or circulation was the enlargement of the superficial veins of the face, neck, chest, and abdomen, particularly of the front of the chest and abdomen, and which was more marked upon the right side than upon the left. The most distressing symptom in this case was dyspnoea. The patient could breathe best when he was sitting up in bed, and pretty freely when lying upon either side, especially upon the left, but it was quite impossible for him for any length of time to lie upon his back with his head low, the dyspnoea became so urgent. Another feature was hoarseness, which had been observed for about three months; and there was this peculiarity about it—that if we made him turn his head to the right shoulder his voice was comparatively clear, but if towards the left, then the hoarseness became decided, and if we made him lie upon his back with his head low his voice became extremely husky. A laryngoscopic examination showed that there was congestion, but no paralysis of the vocal

cords. These symptoms and physical signs pointed to the conclusion that there was a tumour in the anterior mediastinum.

A short time since I saw a somewhat similar case in consultation with Dr. Wm. Pearson. This patient, a female, aged forty-nine, began to complain of pain to the right of the middle of the sternum, which, about nine months prior to my visit, extended up to the right shoulder. This was followed by a hard irritative cough, which was soon accompanied by slight frothy and occasionally tough mucous expectoration. To these symptoms were added distension of the superficial veins of the right side of the neck and face and right arm, and oedema, which was aggravated by exertion. At the time of my seeing her, the cough and expectoration and pain of chest continued, and she had dyspnoea to such an extent that she could not lie down with comfort. The breathing over the whole chest was harsh, but air entered both lungs with equal freedom. There was distinct prominence, associated with dullness on percussion, of the upper part of the sternum, and at the right supra-scapular region the percussion was less clear than at the left. The voice was hoarse, but the pulses were equal on the two sides, and the pupils were unaffected.

But, to return to the case with which we commenced, we felt very powerless as to even palliative treatment. We hoped, however, that by removing the fluid from the pleural cavity there might be some mitigation of the dyspnoea. This was accordingly done on February 16th, twenty-six ounces of inflammatory serous fluid being withdrawn with the aid of Southey's trocar. This, however, was not followed by any diminution of the dyspnoea, showing that it was dependent upon the pressure of the tumour, and little if at all upon the pleuritic effusion. Death put an end to the sufferings of the patient two days afterwards, and on February 20th a post-mortem examination was made by Dr. Joseph Coats, pathologist to the infirmary, with the following result.

The lower limbs show considerable emaciation. There is marked oedema of both upper limbs, especially in the right hand and forearm. Chest: The heart is of normal size. The mediastinum is occupied by a bulky tumour which extends considerably more to the right than to the left side; taking rough measurements it may be said that the tumour in its thickest part extends four inches from before backwards, and five inches from side to side. The main mass of the tumour is in the fork formed by the bifurcation of the trachea, and more behind than in front; but the mass which involves the great veins is somewhat separated from the main mass and is almost equal in size. On opening the pericardium it is seen that all round at the place of issue of the great vessels, the pericardium is involved in the tumour, whose whitish-gray tissue has replaced it, and projected into the sac in lobulated masses. There is no considerable extension to the heart itself, but at the auricles the tumour tissue approaches very near to, and on the left side does involve slightly, the wall of the auricle. On the other hand, the superior vena cava on the one side, and pulmonary veins on the other, have their walls infiltrated and their calibre somewhat encroached on by the tumour tissue. The contraction from encroachment of the tumour is considerably greater in the case of the superior cava and right pulmonary than in the left pulmonary vein. On tracing up the superior cava its wall from the orifice to its division is completely occupied by tumour tissue, and its continuation upwards into the right innominate and internal jugular is similarly involved. The left innominate and right internal jugular are entirely

occluded by thrombi. The right subclavian vein cannot be traced to its junction with the innominate, its wall being apparently converted into tumour tissue and its calibre filled up. Beyond this the vein is occupied, but only for a short distance, by a thrombus. The left branch of the pulmonary artery is not involved in the tumour mass, but the right branch passes through a considerable thickness of it, and its calibre is obviously narrowed; but it is not determined whether its wall is actually involved or not. The aorta is not affected by the tumour. The left phrenic nerve in passing down in front of the root of the lung is impinged on by a projecting piece of the tumour and partly involved in its tissue. The extreme lower part of the trachea and both main bronchi have their walls partly replaced by the tumour tissue, which presents itself internally in the form of rounded whitish nodules. The right main bronchus is much more involved than the left, and for a certain distance its wall is undistinguishable from the main tumour; the tumour also extends a short distance into the lung, along the bronchus and its primary branches. On examining the arteries, it is found that the right subclavian carotid and innominate lie for the most part behind the mass of the tumour. The subclavian is nearer, and would be more pressed on but it is not embedded in the mass. A microscopic examination showed that the tumour was a lymphosarcoma.

Original Papers.

ON A CASE OF EXPLORATION OF THE KIDNEY.

By THOMAS F. CHAVASSE,

Surgeon to the Birmingham General Hospital.

At the present time, when the surgical treatment of kidney affections is attracting much consideration, the case under notice is interesting with reference to the questions of both diagnosis and treatment.

John T—, aged forty-nine, commission agent, admitted into the General Hospital May 15th, 1882. For a number of years patient has consumed a large amount of alcohol; latterly has much diminished the daily allowance. Six years ago he was suddenly seized with pain in the back (the precise position not defined), lasting for some hours. This was followed by a discharge of blood mixed with the urine. He was then told by his medical attendant that he was suffering from a stone in the kidney. Another attack of hæmaturia took place two or three months afterwards, and a recurrence of this symptom has been noted, at varying intervals, down to the present date. The longest period that it was altogether absent has been four months. Of late the frequency of hæmaturia has much increased. On and off the man has been a patient at the hospital for three years and a half. His first visit was to my outpatient room for complete retention of urine and great bladder distension. This, it was found, was caused by the presence of large blood-clots. An examination of the bladder with the sound and bimanually revealed nothing abnormal. In and around the loin no abnormality could be detected. The patient declined to become an inmate of the hospital. From time to time up to admission I saw him, and he was also under the care of my

colleague, Dr. Saundby, and various private practitioners. Large doses of perchloride of iron and ergot seemed to control the hæmorrhage better than any other remedies. The patient was taught how to pass a catheter himself, and could generally relieve the bladder when retention of urine occurred. On admission there was marked anæmia, and it was stated that within the last three months the patient had lost flesh rapidly. The body was, however, fairly well nourished. Pain was complained of in the right lumbar region, passing down the course of the ureter. There was marked dullness in this region, and anteriorly a feeling of resistance on palpation was met with. It was said that "matter" was often seen in the water.

Examination of urine: 40 oz. passed daily, sp. gr. 1023; a cloud of albumen, pus and blood-corpuscles, together with crystals of oxalate of lime.—May 17th: A severe attack of hæmaturia occurred, during which it was necessary to resort to catheterism several times daily.—24th: The pelvis of the right kidney was explored, through an oblique lumbar incision four inches long. An aspirating needle passed into the renal pelvis at several points failed to detect any calculus. Smart hæmorrhage followed these punctures. An antiseptic sponge was inserted into the wound, and left in contact with the kidney until evening, when it was removed, and the edges of the incision united. The patient complained of pain in the regions of the stomach and the bladder; the latter viscus was distended, and on the introduction of a catheter 16 oz. of very bloody fluid were withdrawn.—25th: Morning temperature, 99°; evening, 99·4°. Morning pulse, 102; evening, 112. Antiseptic dressings soaked with bloody serum. Complaints of great thirst and of pain shooting down in the direction of the ureter to the testis of the right side. Urine voided without a catheter.—27th: Urine still bloody; reaction alkaline, sp. gr. 1020, albumen 1·20; blood-corpuscles and crystals of the triple phosphates; marked cystitis. Bladder washed out with weak carbolic lotion. The quantity of urine passed daily for the first week after the operation was 34, 43, 40, 45, 38, 36, and 34 ounces.—June 2nd: Antiseptics discontinued, as the wound is rapidly granulating; by the 5th the more acute bladder symptoms had subsided.—30th: Has had no hæmaturia for three weeks, and is free from pain. The patient went home.—July 15th: Readmitted to hospital owing to another attack of hæmaturia. Urine faintly acid; contains a little albumen, blood, pus, and epithelial cells. Evening temperature 103°. The hæmorrhage continued until July 24th. In the meantime œdema of both feet and ankles had appeared.—31st: Feeling much better, patient at his own request went home. Subsequently he was removed into the country, where he remained for some weeks, and the hæmaturia nearly ceased.

In November I found he had returned to his own home, and was obliged to keep his bed. There was marked œdema of both feet. A large immovable mass could be detected in the region of the right kidney, and the liver was much increased in size. On the upper part of the right thigh, internal to the femoral vein, there was a pigmented sarcomatous-looking growth the size of a hazel nut. In January of this year a semi-fluctuating mass was found over the left external malleolus; this being incised to a slight extent, revealed a mass of granulation tissue (sarcoma?). The growth in the thigh was enlarging, as were also the intra-abdominal masses. Hæmaturia was no longer complained of; no pain existed; took fluid nourishment only. On February 4th the patient died exhausted.

Twenty-four hours after death, with great difficulty, I obtained permission to make a partial examination of the abdomen. On opening the cavity from the front, a very much thickened diaphragm of peritoneum excluded the right kidney from the peritoneal cavity proper. The kidney itself was three times its normal size, adherent in front to the peritoneal reflexion, and posteriorly to the muscles of the back. No distinct supra-renal capsule could be seen. Externally there was a very thin layer of apparently healthy looking cortical substance; internally the organ was a large mass of caseating material. No calculus was to be found. The opposite kidney appeared somewhat enlarged, but otherwise normal. The bladder was empty, and slightly hypertrophied. The liver was much enlarged, and contained many carcinomatous deposits. By cutting through the diaphragm similar deposits were detected in the right lung. The tumour of the thigh was the size of a walnut, but I was not permitted to remove any for microscopic examination. A portion of the renal substance taken from the inside of the organ showed under the microscope nothing definite, merely débris and fatty matter.

The first point worthy of attention is that nearly seven years elapsed from the first occurrence of hæmaturia until death. Could the bleeding have arisen from any cause unconnected with the neoplasm? Post-mortem examination of the bladder and the opposite kidney failed to detect any other condition that could have excited it. The patient himself, an intelligent man, was always looking out for a small calculus, or gravel, to pass per urethram, and, according to his own statement, nothing of the kind ever happened; so I think it is probable that the commencing carcinoma was the cause of the hæmorrhage. It is an acknowledged fact that renal cancer in adults may extend over a long period, but it is rare for the fatal issue to be postponed for three or four years, although Ebstein speaks of a case in which this condition was demonstrated to have lasted eighteen years. In the present instance, during the last three months of life, the amount of blood passed per urethram was hardly noticeable; this may be explained by the increased growth of the neoplasm causing occlusion of the opening into the ureter. With regard to the operation, the exposed pelvis of the kidney was sufficiently explored by a needle to show that no calculus existed, but the subsequent course of the case would lead me to suggest the advisability in similar operations of making an incision into the pelvis itself, and thus ensuring that the examination be more thorough. From other cases met with I do not think such a procedure would materially affect the after-bleeding from the wound. In this instance hæmorrhage was severe, although the kidney was gently dealt with. It is possible that the malignant nature of the disease might account for this.

If the exploration had revealed the precise nature of the case it seems to me to be justifiable to have made an effort to remove the affected organ. Through the lumbar incision made it certainly would not have been possible to take away the kidney *en masse*, neither would it have been an easy matter to have secured the pedicle. By opening the abdomen from the front, the thickened layer of peritoneum found after death, which covered, and was adherent to, the anterior surface of the kidney, would have rendered removal from the front also scarcely possible. A transverse lumbar incision meeting the oblique cut at its upper part would have been most advantageous. In all probability the peritoneal cavity would have been opened, but extraction could have been completed. In a successful case of nephrectomy per-

formed by Mr. Lawson Tait, by means of a transverse incision, the patient rapidly recovered, although the peritoneum was thus opened; in this instance a previously performed laparotomy had failed to effect enucleation of the viscus. Although a correct diagnosis in the present case was only surmised until the lumbar tumour solved all doubts, yet in obscure cases of hæmaturia we have every reason to hope that a thorough examination of the kidney and pelvis, by means of incisions, will aid us in discovering at an early date the precise nature of the renal condition which has to be dealt with. Whether such an exploration will hasten or retard the growth of a malignant neoplasm is a question to be decided by future experience.

Birmingham.

AN ACCOUNT OF THE GENERAL HOSPITAL, INDIAN DIVISION, EGYPTIAN EXPEDITION- ARY FORCE, AT SUEZ,

FROM AUG. 25TH TO OCT. 13TH, 1882.

By Brigade-Surgeon J. H. THORNTON, I.M.D.,

Late in Medical Charge of the General Hospital, Indian Division, Egyptian Expeditionary Force at Suez.

As public interest has been so much aroused by the recent inquiry into the state of the hospitals at Ismailia and Cairo during the late Egyptian campaign, a short account of the General Hospital of the Indian Division at Suez may not be out of place, especially as this hospital has hitherto remained almost entirely unnoticed. It was at first established in the buildings of the Victoria Hospital at Suez, but on Aug 27th, 1882, it was removed to the P. and O. steamer *Hydaspes*, in Suez docks. The number of sick transferred to the *Hydaspes* was as follows:—

Sick of British troops (2nd Batt. Seaforth Highlanders)	10
Sick of Native troops	16
Sick of Native followers	3
Total	29

The *Hydaspes* had brought over cavalry, and was entirely unprepared to receive sick, as the horse-fittings had not been removed from her main deck. By the kindness of Captain Hext, R. N., Superintendent of Naval Transport at Suez, I obtained the services of some carpenters, who at once proceeded to remove the horse-fittings and to fit out the main deck with beds, etc., in accordance with my directions. The sick were kept on deck as much as possible while this work was going on. The *Hydaspes* is a steamer of 2,984 tons, 375 feet in length and 38 feet broad; she has a flush deck fore and aft, with plenty of space, and a main deck provided with numerous large ports admitting free ventilation. A considerable part of the main deck is occupied by the engine-room and boilers, but there is a large space in front and on each side. This space was used for the hospital, and 100 wooden beds were constructed in it of such height as to place the occupants almost on a level with the ports, so as to get the utmost advantage from the breeze blowing through them. Fifteen of these beds, on the port side of the ship, were entirely separated from the rest, and were devoted to the use of the sick European soldiers and their attendants, while the remaining beds, eighty-five in number, were given to the native sick. The orlop decks, fore and aft, were also placed at my disposal, but were only used for stores, as they were unsuited for hospital pur-

poses, having no ventilation except through the hatchways. A small dispensary was constructed on the main deck close to the fore hatchway, and an operation table was made. This was surrounded by canvas curtains so as to form a room for operations, examination of patients, and such like purposes. When not in use the curtains were rolled up so as not to interfere with ventilation. The situation of the ship was very convenient; she was moored close to the sea wall on the south side of the Suez docks, and presented her broadside to the prevailing wind, which blew through her large ports, ventilating the main deck so thoroughly that even at night, when every bed was occupied, I found on visiting the hospital that the air was sweet and not the slightest odor perceptible. As she was close to the shore and provided with suitable gangways, I ordered all cooking to be done on land, and I had latrines dug at a short distance, instead of allowing the ship's latrines to be used. By these means, and by the liberal use of disinfectants in the hospital, the sanitary condition of the ship remained perfectly good from first to last. Condensed water was supplied to the sick from the ship's condensers; the supply was ample and of good quality. The rations supplied by the commissariat department for the use of the sick were of good quality throughout, and I had no occasion to find fault with anything. Although the heat in the daytime was considerable, the thermometer on deck frequently indicating a temperature of 100°, the nights were cool and pleasant, and the climate appeared to be very healthy. The sick rapidly improved, especially those sent down from the front, and hardly any cases took an unfavorable course. It was at one time proposed to bring up the *Hydaspes* to Ismailia; but, taking into consideration the superiority of the climate and sanitary conditions at the Suez docks and the convenient situation of the ship, I recommended that she should be allowed to remain where she was, and that the sick should be sent down to her. This plan was ultimately adopted. In a short time the available space in the *Hydaspes* was all occupied, and the sick subsequently received were accommodated in tents, which were pitched on the shore at a short distance from the ship. Early in October orders were received for the removal of the hospital from the *Hydaspes*, as the ship was required for the transport of cavalry returning to India. Additional tents were accordingly obtained, and the hospital was removed from the *Hydaspes* to the tents, where it remained until all the sick were disposed of by transfer to their respective corps as they arrived at Suez on their way back to India. The sick native followers, ninety-four in number, were placed on board the transport *Avoca*, under my charge, for conveyance to Bombay. They nearly all recovered during the voyage; only one of them died at sea; and the few remaining sick on arrival at Bombay were sent to the hospitals of that city. The total number of patients treated on board the hospital ship *Hydaspes* from Aug. 27th to Oct. 11th was as follows:—

Officers.....	3
Sick of British troops (2nd Batt. Seaforth Highlanders).....	10
Sick of Native troops.....	130
Sick of Native followers.....	180
Total.....	323

The principal diseases among the fighting men were ague, dysentery, and venereal affections. Very few of the cases were severe, and none proved fatal. Some cases of conjunctivitis occurred, but none of them were of a severe type. There were four cases

of gunshot wounds, of which only one (a gunshot wound of the right forearm, missing the bones) could be considered severe. There was also one case of sword wound of the chest, in which only trifling injury had been inflicted. A few cases of bronchitis, pneumonia, and pleurisy were received, mostly slight, and requiring no particular notice. One of the officers suffered from typhoid fever, probably contracted on board the transport in which he came from Bombay to Egypt; his case was serious, but it ran a favorable course, and he was discharged to rejoin his corps on Oct. 10th.

The principal diseases occurring among the native followers were ague, dysentery, ophthalmia, ulcers, and venereal disorders, and they suffered from these affections much more severely than the fighting men. Many of the followers appeared to be weak and sickly men, who should not have been allowed to accompany the expedition at all, and most of them seemed to have contracted a slight scorbutic taint from the combined effects of hard work and insufficient and monotonous diet. Lime-juice of course was freely used in these cases, but fresh meat seemed to be of greater value, not only as nourishment but as an antiscorbutic. Some of the cases of dysentery among the followers proved very intractable and resisted all treatment; nearly all of them were saved by careful nursing and plenty of nourishment, but one proved fatal. This was the only fatal case that occurred in the General Hospital from August 25th to October 13th, the period during which I was in charge. The solution of nitrate of silver (ten grains to one ounce) proved effectual in most cases of ophthalmia when taken in time, but in one unfortunate instance vision had been destroyed before the patient applied for treatment. Most of these cases seem to have occurred through the agency of dirt and flies, the men generally neglecting to wash their eyes and to prevent the flies from settling upon them. Two cases of Guinea-worm occurred, but they presented no features of interest. I watched for cases of hæmaturia from the presence of the bilharzia, but met with none.

In conclusion, I may mention that Rear-Admiral Sir William Hewett, K.C.B., V.O., commanding at Suez, frequently visited the General Hospital in the *Hydaspes*, and approved of all the arrangements.

Monghyr, Bengal.

LIVER ABSCESS PRECEDED BY ACUTE, AND ACCOMPANIED BY CHRONIC, DYSENTERY; CURE.

By J. H. BRANNIGAN, L.R.C.P., L.R.C.S. Edin.

THE following is a short report of a case that came under my notice in April of last year, which from the serious nature of the complaint and the simplicity in the method of its treatment I think worthy of record.

Early in the month above mentioned I was summoned by the American mission to see a certain Giorgis, native of Luxor, on the Nile, Upper Egypt. He was en route for Cairo accompanied by his aged father, there to seek advice and treatment at the hands of some European surgeon. Hearing from the Rev. Dr. Hogg, chief of the American mission in Egypt, that there was an English surgeon at hand, the father and patient begged that I might at once be called in.

Appearance of patient on visit.—The patient, aged eighteen, was tall and greatly emaciated, wore an extremely anxious expression, face mottled, conjunctivæ slightly if at all jaundiced, voice feeble—in short, much debilitated.

History of case.—Six months ago he had an attack of dysentery; this finally became chronic. In the early part of January, 1882, the patient began to complain of pain in the region of the liver, associated with fever, sometimes absent, but always returning, especially in the evening, accompanied by perspiration. He sought advice, and was frequently blistered over the seat of pain. Later on, inability to retain food, which was shortly vomited after taking it. Difficulty in breathing was also noticed; breathing was labored, "thick" as he called it. Prostration went on, and stools to the number of three or four per diem were passed. The temperature was now taken (102° F.); pulse 90. On inspection the abdominal region showed distinct swelling at the epigastrium, and slightly to the left of the middle line. Palpation could not detect fluctuation, but made out an annular hardness on the surface of the tumour, with a depressed centre, easily felt through the abdominal walls.

Diagnosis.—Taking into consideration the history of the case—viz., attack of dysentery some months previously, and now in existence as chronic; presence of a tumour; remittent nature of the fever—I concluded it was one of liver abscess situated in the left lobe.

Exploratory examination.—A fine exploratory trocar and cannula (made by Collin et Cie., Rue de l'Ecole de Médecine, Paris) was inserted at the most prominent seat of the tumour, where I was of opinion adhesions had set up with the abdominal parietes. On withdrawal of the trocar I waited anxiously a few minutes, and was pleased to see a thick creamy chocolate-colored pus appear.

The patient and his father seeing my statements verified by the exploratory examination, no longer mistrusted, but implored me to open the abscess at once. I promised to do so next morning. The question was (a) aspiration, or (b) free incision. The first was not possible, as there was no aspirator. The second, free incision at the seat, where I was confident adhesions had formed, seemed to specially commend itself, aided by the Lister spray. Having no spray apparatus, I adopted a method that would minimize the danger of septicæmia—i.e., insertion of a moderately large-sized trocar and cannula. The night preceding the operation the patient was very feeble after walking to my house from the American mission; felt sick, and complained of the old pain in the hypogastrium. Temperature 104° F.; face flushed, and large beads of perspiration over the forehead. I gave the patient some milk, beaten up with an egg and an ounce of whisky. Sent him to bed in my own house, his future hospital. 8 A.M.: The patient passed a restless night; temperature 102° F. The dressings having been prepared—viz., cotton-wool, saturated in 1 in 20 carbolic acid lotion, and some folds of Lister's antiseptic gauze, with oiled silk—I carefully sponged the abdominal surface with 1 in 20 carbolic lotion, selected the point of annular hardness, raised up the skin, and made an incision, in order to render penetration of trocar and cannula painless. I then took out of a solution of 1 in 20 carbolic acid lotion the trocar and cannula, drove them well into the tumour, and withdrew the trocar. Immediately more than two pints of healthy pus, mixed with liver débris, came away. No more pus coming, the parts were carefully sponged with 1 in 20 solution of carbolic acid, tied in cannula, and placed a piece of oiled silk round it at the orifice of the wound, to obviate any absorption of pus; carbolized cotton-wool was placed round to prevent any filtering of pus at the edges of the dressing; over the whole the Lister gauze was placed, and kept *in situ* by a large towel passed round the body and fixed at the side by

three safety pins. The patient expressed himself much relieved, and shortly after took some milk beaten up with egg and whisky. 8 P.M.: Dressing removed; a few ounces of pus had oozed out of cannula. I applied a fresh dressing after cleaning the parts carefully in 1 in 20 carbolic acid lotion. Temperature 103° F.; sweating on forehead slight; no pain, no sickness; had had milk and some chicken broth. The usual dressing was continued twice daily, the pus still continuing healthy. The cannula remained in twelve days without causing any irritation save a slight blush at the point of insertion. Attention was paid to the diet, and stimulants in the shape of claret were given. The discharge had now almost ceased; the swelling disappeared, and one morning the cannula was found two-thirds out and no discharge visible. I removed the cannula, replacing it by a drainage-tube previously dipped in 1 in 20 carbolic acid solution. Examination of the cannula showed the part that was in the abscess to be discolored by the bile acids. Temperature never varied from 99° A.M. to 101° P.M.; pulse 75 to 80. The appetite was good, and food in the shape of milk, eggs, and chicken broth was partaken of with relish. The breathing became free, and the sickness ceased from the day the abscess had been evacuated. Third week: The dressing tube was now difficult to introduce, and no discharge visible; still I could detect a slight return of swelling, there was a rise of fever, and an outbreak of perspiration over the forehead. I reintroduced the trocar and cannula, previously dipped in a 1 in 20 carbolic lotion, withdrew the trocar, and about three ounces of pus, mixed with liver débris, came away. This was the last discharge in any quantity. The case went on rapidly well, and in twenty-three days the patient left cured, restored in flesh and strength—a different person to what he was when first seen.

About this time I saw in THE LANCET some reports on the use of nitrate of silver in enema in a case of chronic dysentery. At the end of the second week I gave an enema of twenty grains of nitrate of silver to three pints of tepid water, without any effect. Then an enema later on of forty grains to three pints of water. Stools were less. Finally I gave sixty grains of nitrate of silver to three pints of water, and although the fluid was retained about four minutes it caused no pain. After this stools, three, two, and one, of more solid consistence, were passed, and before the patient left he had not more than one stool daily, and that healthy in appearance. All through the pus was free from smell and quite healthy.

CASE OF DIABETES; DEATH THIRTY HOURS AFTER FIRST VISIT.

By ED. GEO. WHITTLE, M.D. Lond., Etc.

SHARING in the general sympathy which the harsh censure of Dr. Blades has evoked from the profession, I am induced to send you the following report.

On Monday, June 25th, I was called to see a man whom I found lying helpless in bed, with his feet hanging over the side and uncovered, as though he had failed in an attempt to get back. He looked about thirty-five years of age, muscular, spare, but not emaciated; his hands and feet were cold and cyanosed; his breathing was laborious, rapid, and deep; he could answer questions, but so slowly and with such evident effort, that I put no more than were needed to ascertain that he had his mental faculties. The pupils were equal; there was no paralysis, but when the eyelid was raised, it fell back sluggishly. Chest walls were

highly resonant, and the respiration was everywhere loud, harsh, and bronchial, expiration being almost as loud and long as inspiration. Heart healthy. Mucous membrane of lips and eyelids red. Tongue dry and brown. Throat dusky red, with vesicular eruption on soft palate. Pulse 140; temperature 97.8°. Urine (none saved) reported to be healthy in appearance; micturition normal. There was neither oedema nor anæmia. The case was clearly one of diabetic dyspnoea, running rapidly to a fatal issue. He soon became unconscious, passed his urine in bed, and died on the evening of the next day. I certified without having examined the urine.

The following is the history as obtained from his wife. Had always been healthy and temperate. A year ago he was treated for an attack of diarrhoea, but had had no medical advice since, nor had he missed a day's work (shoemaking). On June 19th, a week before death, he had sore-throat. On the 21st his wife wished to send for a doctor, but he said there was no need, as his throat was getting better. For some few weeks he had occasionally complained of fatigue, which he attributed to the hot weather. His sight was slightly impaired. This, he thought, was due to sitting too closely at work. He worked as usual on the 23rd (Saturday), but in the evening felt tired and drowsy. The next morning he felt as well as usual, but his wife induced him to remain in bed for the sake of rest. He had no symptoms causing anxiety to himself, and it was only on account of his throat that his wife wished him to have medical advice. On the 25th he arose at 6 A.M., and his wife observed that his breathing was short while dressing. About 1.30 P.M. I saw him in the condition above described.

Remarks.—Having the advantage of the knowledge derived from a study of Dr. Blades' case and a paper read by my friend, Dr. E. Mackey, in which the diagnosis between hysteric, uræmic, and diabetic dyspnoea was ably pointed out, I was saved all trouble in diagnosis. To remove all doubt, however, I drew off some urine after death. It contained albumen and sugar in abundance. I am not ashamed to confess that had this man consulted me on the Friday evening before his death he might possibly have left me with his glycosuria undetected. Very few men in general practice examine the urine at a first consultation as a matter of routine; but unless this rule be observed, anyone may overlook an obscure renal affection, accepting the suggestion of the patient that his malaise is due to overwork, confinement, heat of the weather, etc. Are we to be held almost criminally responsible in such cases when the inevitable and natural sequence occurs without its having been prematurely announced? Are we who have the most complex and inconstant phenomena of disease to interpret never to be forgiven an oversight? We cannot avoid them. He who asserts that he cannot err must have had but little experience in the practice of medicine, and I should be sorry to trust myself to his infallibility. Are not most cases of glycosuria, as of albuminuria, already chronic when they first come under notice? Is it not often impossible to assert when they began? The above case will be classed by many as "acute diabetes"; but if I assert that the man may have had glycosuria for many years, who is to prove the contrary?

Brighton.

—The Brazilian Government has awarded a gratuity of £3,500 to Dr. John Baptist Lacerda for his discovery of the antidotal virtues of permanganate of potash in relation to snake-poisoning.

THREE CASES OF CHRONIC OSTEITIS OF THE LOWER ENDS OF TIBIA AND FIBULA.

By R. W. GREENISH, F.R.C.S.,

Late House-Surgeon, Ashton-Under-Lyne Infirmary.

THE somewhat unusual occurrence of three patients with chronic osteitis of the same bones in a hospital together, and some points connected with the treatment, have induced me to place these cases upon record; and I have to thank Messrs. A. Hamilton and W. H. Hughes, surgeons to the institution, under whose care the patients occurred, for permission to do so.

CASE 1.—E. N., aged seventeen, cotton weaver, was admitted into the Ashton Infirmary, under the care of Mr. W. H. Hughes, on Sept. 1st, 1880. She stated that six years before admission she injured the right ankle by falling with the leg doubled under her; the ankle felt weak for a fortnight or so, but became quite strong again till three years ago, when it began to feel tired, and since then has been steadily getting worse. The ankle has been larger than the other for two years, and for twelve months has been so bad that she has been unable to put the foot to the ground. Nothing of importance in previous or family history. Patient was thin, otherwise healthy. On the right leg there was a marked enlargement of the lower two inches of the tibia, which was fully half as large again as that of the left side; it was hot to the touch and extremely tender; the soft parts in the neighborhood were somewhat swollen, and below the tip of the inner malleolus there was a fluctuating swelling. The lower end of the fibula was also much enlarged, and extremely tender. The pain was of a dull aching character, and much worse at night. For the first five weeks the patient was kept in bed and an evaporating lotion applied; from half a grain to a grain of opium was required every night to obtain sleep. On Oct. 24th an incision was made over each malleolus down to the bone. On the 26th the patient was free from pain.—Nov. 11th: Pain had gradually reappeared, and is now as severe as previous to operation.—Dec. 22nd: This morning the lower ends of both tibia and fibula were trephined, an ordinary cranial trephine being used; on the tibia a hole three-quarters of an inch deep was made, the bone being so soft as only to be removed in pieces; on the fibula a cylinder of bone an inch in depth was taken away; the bone appeared rather more dense than normal cancellous tissue. No cavity was reached. Dressed with carbolic oil.—Dec. 26th: No pain.—Jan. 1st, 1881: Pain returning. On Jan. 7th pain was as bad as before the operation, and on Feb. 17th it was noted that the pain was not constant, being some nights quite absent.—April 4th: Pain very severe every night. The fibula is still tender, but the tibia only on very firm pressure.—24th: An incision was made this morning over the fibula, and several holes were made with an Archimedean drill.—May 7th: The pain not so severe as previous to the last operation, and is still tender over the fibula and between the bones in front.—June 24th: The patient was discharged, her condition being about the same as described in the last note, requiring morphia nearly every night. From the present house-surgeon, Mr. Payne, I now hear that the patient was readmitted in September, and had the fibula gouged, after which she was almost well, having only slight pain in the tibia. The measurements of the ankle were interesting. On Nov. 6th, 1880, the right measured 10 in. in circumference, as against 8 in. for the left; on Feb. 17th, 1881, the right measured 9½ in.; April 4th, 9 in.; showing a

decrease of 1 in. On admission some trials were made with Sequin's thermometer to ascertain the hottest part of the affected ankle, with the result that over the fibula 6° were registered, against $4\frac{1}{2}^{\circ}$ over the inner malleolus and $3\frac{1}{2}^{\circ}$ in front of the ankle.

CASE 2.—E. B.—, aged twenty-one years, weaver, was admitted on March 20th, 1881, under the care of Mr. Hughes. Eight years ago she sprained her left ankle and was laid up one year with it. She got better, but still had pain in it after a long journey. Two years ago the pain began to get worse, which she attributed to having to stand longer hours at her work. Had worked up to the time of admission, but often only two or three hours a day. Patient was to all appearance in perfect health. The lower two inches of tibia and fibula of the left foot were enlarged, the tibia being quite half as large again as on the right side. Measurement gave one inch increase, and Sequin's thermometer showed $\frac{3}{4}^{\circ}$ greater heat. The pain was so severe as to require morphia every night. As rest in bed and counter-irritation produced no improvement after a month's trial, it was decided to trephine both tibia and fibula, as in the previous case. After the operation the patient was quite free from pain, and when last seen, seven weeks later, there had been no return.

CASE 3.—H. W.—, aged sixteen, piercer in a cotton-mill. Ankle has been bad seven weeks, but the pain did not commence till a fortnight later. Can give no cause for it. The pain is severe, but only at night. The patient is fairly healthy looking, but has enlarged submaxillary glands. The lower three inches of tibia of left side are enlarged to nearly double, and somewhat tender to pressure; fibula is also enlarged, but not to the same extent. Sequin's thermometer showed 1° to $1\frac{1}{2}^{\circ}$ more warmth for the affected ankle. On March 29th, 1881, an incision was made antiseptically along inner malleolus down to the bone. After the operation the patient still complained of pain, though it was not so bad.—April 26th: Measurements showed a circumference two inches in excess of the right. On April 30th an abscess appeared over the lower end of the fibula, which was subsequently opened and healed without any trouble. On June 8th there was a diminution of half an inch in the size of the ankles; no pain. By June 27th he was able to walk without any pain. The subsequent history, however, showed that the relief was only temporary. In November both bones were trephined, after which he was again free from pain.

Cases in which an abscess or abnormal cavity has been found, on trephining a bone for chronic disease, are not uncommon. Thus out of 34 cases that I have been able to collect¹ in which this operation had been performed, one of these two conditions was found in no less than 30 of the number, while in four only could no trace of either pus or cavity be seen; of the 30, pus was found in 22, and a simple cavity in 8. It is, of course, impossible in the cases I have reported to assert positively the absence of a minute abscess, as this might very well have been overlooked; still it must have been very small, as nothing of the kind was noticed during the operation, and no subsequent discharge of pus took place. An interesting point in these cases seems to be the complete, though temporary, nature of the relief obtained from simply incising the periosteum; this is, I think, to be attributed to the transudation, which takes place through the bone, between the medullary cavity and the exterior; this would relieve the tension inside, but would cease as soon as the

surface became covered with granulations. Whether any operation short of trephining would have given sufficient relief is doubtful, and to judge from the first case it is probable that linear osteotomy, as recommended by Mr. Erichsen, would have been only of temporary service.

One point in which these cases differ from those that I have seen reported is the fact that both bones were affected, and to a nearly equal degree, so as to require an operation on both. In only one were there any constitutional symptoms that might be held to account for it; in both the others could the disease be traced to an injury. Bearing on this is a fact which I have noticed in compound wounds of the ankle—viz., that in all the cases I have seen, four in number, where the injury was limited to one side of the joint, there has occurred an abscess on the opposite side of the joint, and which in three healed without any trouble. In the third case, given above, a simple incision over the tibia was followed by an abscess over the fibula. These cases are too few to allow of any conclusions being drawn; still I think they point to some sort of relation existing between the two epiphyses, possibly through the blood or lymphatic channels, so that disturbances in the one may be transmitted to the other, similar perhaps to the periostitis which is so often seen as a result of osteo-mylitis.

London, N.W.

REMARKS ON A CASE OF SO-CALLED HYSTERIA.

By J. B. FOOTNER, F.R.C.S. Eng.

ABOUT eight months ago, a well-nourished though somewhat anæmic young woman, unmarried, aged twenty-five, came to me for advice. She said that she had recently lost the use of her right thumb, and that her right arm was weaker than the left. She could not account in any way for this. About a year previously she had had sores on the right wrist, which, she said, took a very long time to heal. Apart from this her general health was fair, with the exception of some slight dyspeptic derangements. On examining the right arm, it was not found to be wasted as compared with the left; the muscles of the ball of the thumb were, however, distinctly so, probably from disuse. I treated her by the application of the interrupted current to the muscles of the arm and thumb, and gave her arsenic internally. The arm and thumb soon began to improve under this treatment.

About a month after her first visit she informed me that some sores similar to those which she had had a year ago had broken out on the back of her right hand and wrist. These sores presented a peculiar appearance, quite unlike any normal pathological process. They were about three-quarters of an inch in length and one-quarter of an inch in breadth, longitudinally oval. They resembled very much the appearance produced by a blister with the cuticle entirely removed, and no sign of it left, but only a bare raw surface bathed in serum. There were next to no traces of inflammation. The sores were four in number, each of similar size, shape, and appearance, and in the long axis of the limb. I ordered the application of zinc ointment.

She returned after a few days. The sores were no better, and had evidently been irritated. Having no doubt of this latter fact, it seemed to me the best plan would be to cover the sores with strapping extending continuously from below the situation of the sores to above them, as one straps

¹ Reported by Gosselin, Duplay, Porter, Trélat, and Morris.

an ulcer of the leg. This was done, and as she could not get at the sores they quickly healed. The strapping was continued for a fortnight afterwards. The ulcers were very soon reproduced, and also another of exactly similar appearance longitudinally over the insertion of the right deltoid. Strapping was again applied, and continued for four weeks, in the hope that by this time the patient would have forgotten about the sores. After this, for a week or two no ulcerations appeared; but soon she came again, with similar productions round the mouth just bordering on the lips. It was manifestly impossible to apply strapping here, so lunar caustic was freely rubbed over the raw surfaces, hoping that the pain would act as a deterrent, and it did. She continued free from sores after this. Her right arm and thumb are now as strong as the left.

Quite recently she has reappeared with sores on the same wrist as before, for which I am adopting the same treatment. Had this been a hospital case I should probably have been able to discover how the sores are produced; but as she has a father a chronic invalid and a mother just recovering from hysterical paraplegia and aphonia (a bad nervous family history, be it remarked), it was useless to expect any assistance from them, and quite possibly they would not have believed that their daughter was the originator of the sores. I think the best course was to endeavor to outwit the patient.

A very interesting case at the North-West London Hospital of a somewhat similar character is reported by Dr. T. Colcott Fox in *THE LANCET*, a short time since. In this case the girl confessed she had produced the sores partly with her nails, but mostly by continual rubbing with the tops of her fingers. It seems probable that the cause in my case is similar. Her right arm being weak, it can be readily imagined that she would use her left arm to produce these phenomena. She is not naturally left-handed.

Tunbridge Wells.

SCARLET FEVER IN ITS RELATION TO THE PUERPERAL STATE.

By J. T. BURGESS, L.R.C.P., L.R.C.S. Edin.

THE two following cases are interesting, and, I trust, worthy of record as illustrating a connection between the scarlet and puerperal fevers. They at the same time throw some light upon the questions relating to the period of incubation and to the vitality of the contagious principle of the former disease. Lastly, they painfully demonstrate the fearful responsibility that devolves upon the medical practitioner towards his lying-in patients during the time he is in attendance upon scarlatinal cases.

On Nov. 20th, 1882, Mrs. A—, aged twenty-two, residing temporarily in an isolated cottage in a sparsely populated district, was delivered of a first child. The labour was tedious, and eventually was terminated with forceps, the child being stillborn. The mother, however, progressed satisfactorily until Saturday, Nov. 25th, when she became somewhat feverish, and complained of sickness and diarrhoea. The next day (26th) the throat was sore, temperature 102° , and a slight rash was noticed on the upper parts of the body. This, during the next few days, became of a bright uniform scarlet, ran the usual course of a scarlatinal eruption, and was followed by free desquamation. Thus far no other complication had arisen, but on Wednesday (29th) a change for the worse occurred: the temperature, which had become

almost normal, rose to 103° , the body became tympanitic, lochia slightly offensive, and intellect clouded. A hospital nurse was at once sent for, and the next day a consultation was held with a neighboring practitioner. Symptoms of exhaustion, however, such as muttering delirium, picking at bedclothes, dry brown tongue, etc., set in, and the tympanites increased. Patient sank on Sunday morning, Dec. 3rd, thirteen days after delivery, the temperature, as taken by the nurse shortly before death, having reached 106° . The origin of the poison in this case was at first difficult to discover. There had been no recent case of scarlet fever in the neighborhood, and I failed to trace any exposure to infection on the part of patient, nurse, or medical attendant. The following is the only solution of the problem, which, after most careful inquiry, presents itself. The patient, upon marriage, was compelled to make temporary use of a cottage which had been empty for some time, and was condemned to be pulled down. The occupants of this cottage, who left it twelve months previously, had all suffered from scarlet fever, and the house had never been disinfected. The bedroom in which my patient was confined had to undergo a certain amount of preparation immediately before the event came off, and amongst other things, in order that the fire-place might be available, a quantity of old sacking was removed from the chimney. To this disturbance I am inclined to attribute the setting free of scarlatinal poison.

Whilst in attendance upon the above, I was called upon, Dec. 1st, to attend M. G—. This patient resided seven miles distant from the previous case. There had been no scarlet fever in her village, nor, as far as could be ascertained, could she have had communication with anyone suffering from that disease. M. G— was twenty-two years old, unmarried, and was prematurely delivered in the early morning of Dec. 2nd of a small weakly child which died during the day. About 11 A.M. the patient had a slight convulsive seizure, to which no importance was attached, as the girl had frequently shown symptoms of hystero-epilepsy during the two previous years. On Monday Dec. 4th, however, a severe rigor took place in the afternoon, followed by a feverish state at night. A dose of castor oil was administered, after which a troublesome diarrhoea persisted for about a week. On the 5th the throat became sore, and the feverish state continued. On the 6th I was called up at midnight, and found the patient delirious and more feverish, the throat much inflamed, but no appearance of rash. On Saturday evening (8th) the patient was decidedly worse. Irregular patches of dull red eruption were visible on various parts of the body, delirium had increased, the abdomen was greatly distended, and exhaustive symptoms were becoming prominent. During the next week there was very little change, except that desquamation manifested itself and went on freely. The urine, though at first scanty, was passed in fair quantity, but was slightly albuminous. The diarrhoea ceased, and it became necessary to administer aperients. All this time the body remained much distended and painful in the hypogastric region. On the 16th the patient complained of pain in left side of thorax, which was easier on the 17th, but worse on the 18th, when the respiration was 38, pulse 158, and temperature 103° . There was some dullness at the left base and a slight rubbing sound above, probably pleuritic. The next two days saw symptoms somewhat better, but on the 21st there was a decided change for the worse. Pneumonia and the greatly distended abdomen were together telling upon the respiratory function, respiration being

48, pulse 174, and temperature 104° 6". The skin was pale, lips livid, and face anxious-looking, though the delirium had passed away. After again rallying on the 22nd, the patient sank from exhaustion on the 25th. On the 17th, a younger sister in the same household, who had been in close attendance upon the patient, became feverish. On the 18th rash appeared, accompanied with slight sore-throat, and during the next few days she passed through a mild attack of scarlatina.

That the foundation disease in both these puerperal cases was scarlet fever can scarcely admit of doubt. The clinical history of the first case was well nigh typical, and any shade of hesitation about the second was dispersed by the appearance of the disease in the younger sister. Had this second case stood alone, the real nature of the foundation disease might possibly have been overlooked, owing to the irregularity of the eruption both as regards time and appearance, notwithstanding the presence of sore-throat and subsequent desquamation. The more important complications appeared to take the form of serous inflammations, and to be exaggerations of the after-consequences rather than of the primary symptoms of the disease. If we accept the theory that the first case received its contagion from the cottage itself and on the day of confinement (Nov. 20th), we find a period of five days to have elapsed before the first manifestations of symptoms. In the second case, supposing the medical attendant to have conveyed the infection at the time of parturition, the period of incubation was only three days. In the young girl's case it is difficult to state any definite period of incubation, since it is impossible to fix the exact date upon which she received infection. In the absence of other explanation the first case tends to prove that the vitality of the scarlatinal germ may, under favorable circumstances, continue for at least twelve months, a period much beyond its usually allotted span. It is needless to add that, as soon as the suspicion of the nature of the second case dawned upon me, I at once gave up attending puerperal cases and continued to do so till a month after the death of the patient. During that time I thoroughly fumigated all clothing, instruments, etc., and submitted myself frequently to disinfectant baths. I am thankful to say that, on renewal of midwifery practice, no further calamity has occurred.

Spillsby, Lincolnshire.

MALARIOUS CHOLERA.

By HENRY BLANC, M.D., M.R.C.P. Lond.,

Surgeon-Major, Her Majesty's Indian Army.

PERNICIOUS malarious fevers have not received in this country the attention they deserved, and by most English authors they are either entirely overlooked or the possibility of their existence merely mentioned. In the official Nomenclature of Diseases, the "*fièvre pernicieuse*" of the French is made synonymous with *febres pestiferæ singularum regionum*, and the explanation given in the column of definitions shows that these fevers are not clearly understood. Pernicious fevers are there said to belong to the class of remittent fevers, but this is not the case, and the difference between a malignant remittent fever and pernicious fever is very considerable. Pernicious malarious fevers are essentially of the intermittent type, leaving during the intermission some stray symptoms of the pernicious attack, sufficient in most cases to greatly obscure the diagnosis. We know that the ordinary intermittent fever may prove dangerous in

many ways: to the young by convulsive attacks, to the old and weak by exhaustion, to some by rupture of the spleen, to others by the excessive elevation of temperature and consequent paralysis of the heart. In all such cases we have not to deal with a pernicious fever, but with an ordinary intermittent, in which the action of one of the stages is excessive or the individual is unable to resist the violence of the morbid action. The true pernicious fever personifies (if I be allowed to use that expression) some other disease—apoplexy, tetanus, meningitis, pneumonia, cholera, etc. The special symptoms show themselves either at the first or second paroxysm or, more rarely, at a later date, increasing in intensity and danger with each returning paroxysm; so much so that if the presence of the pernicious fever be not diagnosed at once, it is seldom that the patient recovers from the second attack; never, as far I am aware, from the third. Pernicious fevers are more frequently seen in some localities than in others; but in large epidemics of malarious fevers, irrespective of locality, some cases are generally met with, and doubtless many deaths returned as due to pneumonia, meningitis, cholera, etc., would have been entered under the name of intermittent fever were this exceptional type of fever more generally known and its protean forms even suspected when dealing with sudden and violent sickness in a malarious locality. Malarious fever prevailed to a greater extent at the Yerrowda Central Gaol during 1875 than at any previous time since 1866, the date when the locality was first inhabited. From April, 1875, to March, 1876, the period during which I have been in charge of this gaol, no less than 1,653 cases of intermittent fever, 93 of remittent fever, and 10 of pernicious fever, were admitted into the gaol hospital. The ten cases of pernicious fever consist of 1 apoplectic, 1 tetanic, 2 congestive, and 6 choleraic. The first four mentioned have been already well described by Continental authors, hence I will limit myself to those affecting the choleraic form, as such cases have not been, as far as I am aware, previously recorded, and also on account of their special interest to Indian medical officers, this form of malarious poisoning being so much like cholera.

I endeavored to ascertain if any case of pernicious fever had occurred in previous years at Yerrowda, but the inquiry was surrounded by great difficulties; however, I found that in November, 1874, a fatal case of cholera had occurred. It is during November and December, the drying-up season, that malarious fever prevails here to a considerable extent, and it was during that season, in 1875, that most of the cases of pernicious fever were observed. On reading over the notes of that case of cholera (?) I was struck with its analogy to the cases of malarious cholera, and my assistant, Mr. Daniel Benjamin, a very able and experienced man, and who had attended the fatal case of cholera observed in November, 1874, states that it was entirely like the malarious cholera we were then observing. Evidently the able medical officer, at the time in medical charge of the gaol, had been puzzled by the appearance of this stray case of cholera, and unable to find a better explanation he attributed its occurrence to the patient "lying on the cold stone floor," a cause of cholera as yet scarcely accepted. Vomiting at the outset of an attack of intermittent fever is a phenomenon commonly seen; purging, although less frequently met with, is occasionally witnessed, and some degree of collapse is sometimes observed during the cold stage when this period is intense and prolonged; but these accidental symptoms are seldom combined, and they are pathologically as different from a case of pernicious malarious fever of

the choleraic type as an ordinary attack of vomiting and purging is from true cholera itself. In this country, where cholera lurks everywhere and knows no season, it is of great importance that the existence of a disease, the outward manifestations of which are so similar, should not be ignored. Treatment in the two diseases is very different, and non-interference, which now-a-days is almost the best course to adopt in true cholera, would be followed by very fatal results in malarious cholera; moreover, a more extended knowledge of this disease will doubtless explain many of the strange cases of cholera, whose appearance seems unaccountable, and apparently contradict the influence of human intercourse and the rôle played by choleraic discharges on the development and spread of Asiatic cholera.

CASE 1.—Sawlai Ramma, a Hindoo, under a seven years' sentence, of which half had been spent at Yerrowda, about thirty-five years of age, of a weakly constitution, was admitted into the gaol hospital on November 30th, 1875. The patient says that at 1 p.m. on the previous day he had an attack of intermittent fever, but it was not very severe, hence he did not apply to be admitted into the hospital. Since about noon to-day he feels very ill, and during the last half hour he has been purged four times. The motions are watery, contain some mucus, and are slightly tinged with blood. He vomited several times, first some food, and afterwards some watery matter; the skin is moderately warm; pulse weak, small, infrequent; tongue dry and coated; and he complains of slight abdominal pain. 5 p.m.: He has been purged five times and has vomited twice since last report; the discharges are watery and copious; the stools contain a little mucus. He complains of great thirst, of a burning sensation in the epigastrium, of severe cramps in the lower extremities and in the abdomen. The countenance is anxious and pinched, the voice husky, the skin cool; temperature in axilla 97.4°; the pulse filiform, 84; respiration hurried, 36; the extremities and the tip of the tongue are quite cold and the urine suppressed. 7 p.m.: He is apparently sinking; pulse hardly perceptible; tongue cold and clammy; features shrunken; great restlessness; but no vomiting or purging since the last report. 9 p.m.: Reaction setting in; pulse felt at the wrist; tongue somewhat moist and still cold at the tip; temperature in axilla 98°; urine suppressed. 10 p.m.: Good reaction; pulse weak, no cramps; no purging or vomiting; temperature 98.4°. He spent a good night, and towards morning passed a few ounces of high-colored urine, free from albumen. There was no return of the paroxysm. The following mixture during the attack was prescribed; half a drachm of chlorodyne in an ounce of camphor water, repeated every second hour; also frictions, hot-water bottles to extremities, sinapisms, turpentine stupes, spoonful of arrowroot and brandy. Twenty grains of the hydrate of chloral were given when the reaction had fairly set in. An hypodermic injection of five grains of sulphate of quinine was made early the following morning, and repeated at 9 a.m. Quinine was continued for several days, some also being administered by the mouth.

CASE 2.—Ajoo Kesra, under sentence for life in the Yerrowda gaol two years ago, aged about forty-five, general health good; was frequently in hospital on account of intermittent fever. On August 8th, 1875, he was admitted into hospital. 4 p.m.: The paroxysm of fever began at 10 a.m., with rigor; the last stage set in early, from which he was still suffering when, at 4 p.m., he was suddenly seized with vomiting and purging; the dejecta were abundant and watery, at first tinged with

bile, afterwards slightly with blood; tongue dry; complains of thirst and headache. Temperature in axilla 101°; pulse frequent.—9th, 8 a.m.: Vomiting and purging very frequent during the night; the discharges are watery, occasionally tinged with bile or blood; pulse small, weak; features shrunken; skin shrivelled; urine suppressed; temperature in axilla 98°. 5 p.m.: Passed a pretty good day; towards 4 p.m. vomiting and purging returned; pulse very weak; extremities cold; no cramps; passed some urine towards noon. Temperature in axilla 100°; pulse frequent, 112.—10th, 8 a.m.: Purged six times and vomited twice during the night; evacuations quite watery, not tinged with bile or blood. Since the morning he seems much improved. Pulse 80, regular; temperature in axilla 98°; passed some high-colored urine this morning. The patient quickly improved from this date; there was no return of the choleraic symptoms or of fever, the reaction was quiet, and he seemed to pass at once from severe illness to convalescence. On Aug. 18th he was discharged well. The treatment was the same as in Case 1. The second day, beyond the hypodermic injection of quinine, ten grains of the salt were given by the mouth. The quinine was continued for several days after perfect recovery.

CASE 3.—Goabye, a Chinaman, under a fifteen years' sentence in Yerrowda since ten years, a tall man of a weakly constitution, was admitted into hospital for intermittent fever on November 20th, 1875; he had suffered from two attacks previous to admission. The paroxysm sets in daily at 10 a.m. with rigor, and subsides at 4 p.m. with slight perspiration.—22nd, noon: He is suddenly seized with vomiting and purging; within an hour he passed three copious watery motions tinged with bile; he vomited four times during the same interval, the vomited matter being watery and abundant, at first tinged with bile, afterwards quite clear. He complains of a painful feeling of sinking at the epigastrium and of severe cramps in the lower extremities; eyes sunken; countenance anxious; features shrunken; great thirst; skin cool and moist. Temperature 98.1°; pulse weak, 98; respiration somewhat hurried, 30. 2 p.m.: Has passed two watery motions in bed; no vomiting; skin cold and clammy; tongue cold at the tip; pulse hardly perceptible; cramps in the legs very severe; eyes deep set; features shrunken; skin shrivelled; urine suppressed; voice husky. Temperature in axilla 97.2°; breathing hurried, 40. 4 p.m.: Slight reaction is setting in; skin moderately warm; countenance anxious; pulse felt at the wrist but weak and slow; tongue dry; no purging; cramps less severe; complains of great thirst; urine suppressed. 5 p.m.: Improving; passed some dark-colored urine. Temperature 98.2°. 8 p.m.: Beyond considerable weakness feels well. Temperature in axilla 98.4°; pulse 82, soft and small; thirst less urgent. There was no return of fever or of choleraic symptoms. The convalescence was rather slow. He was discharged on the 28th. Same treatment as in Case 1.

CASE 4.—Toolsee Sewa, undergoing a sentence of seven years at Yerrowda since two years, of a good constitution, age about thirty, was admitted into the gaol hospital on December 8th, 1875, suffering from quotidian intermittent fever. He had an attack on that day, beginning at 9 a.m. with rigor, and subsiding at 3 p.m. with free perspiration. He had suffered previously from several attacks of intermittent fever, and had been treated for that disease in September and November of the same year.—9th, 4 p.m.: The paroxysm began as usual at 9 a.m. with rigor; at noon he felt very sick, and vomited some watery matter; since then he vomited freely four times and passed copious watery

stools, sometimes tinged with bile, others of a slightly reddish tinge. The pulse is small, weak, frequent; countenance anxious; eyes rather shrunken; tongue cold at the tip; urgent thirst; complaints of severe cramps in the legs, of a burning heat in the epigastrium; voice husky; temperature in the axilla 99.2°; urine suppressed; breathing hurried, 32. 7 p.m.: Vomited only once since last report. Pulse improved; extremities not so cold; no cramps; urine still suppressed; temperature in axilla 98°.—10th: Passed a good night; no return of vomiting or purging; skin moist; temperature in axilla 98.2°; pulse well felt, 76, small and compressible; has not passed any urine. 2 p.m.: Doing well; pulse 84; temperature 98.6°; respiration 20; passed a small quantity of urine of a deep amber color, specific gravity 1024, slightly acid, no albumen. He continued to improve, and was fairly convalescent when, on the 17th, he had a return of intermittent fever, beginning with rigor at noon and subsiding at 4 p.m. with profuse perspiration. Large doses of quinine were again administered, and since then he had no return of fever. He was discharged well on January 29th, 1876. The same treatment as in Case 1.

CASE 5.—Purrage Poonja, undergoing a seven years' sentence, at Yerrowda since four years, age about thirty-two years, of a good constitution, had suffered from intermittent fever previously, but is now free from it, and had been transferred to the surgical ward, some boils having broken out on his legs.—August 13th, 7 a.m.: At midnight he was seized with vomiting and purging; during the night he vomited and purged four times. The evacuations were copious, watery at first, tinged with bile, afterwards clear; he looks tired; the features are drawn; the eyes somewhat sunken; the skin cool; the extremities cold; temperature in axilla 97.3°; pulse very small and weak, 84; complaints of slight cramps; has not passed any urine. 5 p.m.: No return of the vomiting and purging; reaction pretty good; pulse 92; temperature in axilla 100°; great thirst; had passed a small quantity of dark-colored urine; complaints of much weakness. 14th, 7 a.m.: No return of vomiting or purging; features more natural; pulse equal, regular, 88; temperature in axilla 100°; has passed water freely. 5 p.m.: Doing well. The case was a mild one; the recovery was rapid; he was discharged well on Aug. 17th. The treatment was the same as in Case 4.

CASE 6.—Teepia Laddo, undergoing a seven years' sentence, at Yerrowda since three months, aged about thirty years, of a weakly constitution, was admitted into hospital at 4 p.m. on December 1st, 1875, presenting the following symptoms:—He was suddenly seized with violent purging and vomiting, and previous to admission he had already passed several copious, colorless watery stools, the vomited matter being at first tinged with bile, afterwards quite clear. The countenance is anxious, the eye sunken, the voice hoarse, the skin clammy and cold; temperature in axilla 97.2°; pulse very small, weak, and frequent, 120. Complaints of great thirst and of severe cramps in abdominal muscles; slight cramps in the lower extremities; breathing hurried, 36. 4 p.m.: Has been purged and vomited several times; temperature in axilla 98°; pulse very weak, less frequent, 108. General symptoms the same; urine suppressed.—2nd, 7 a.m.: No vomiting since last report; passed a semi-liquid stool this morning, bilious-looking. Urine still suppressed; skin dry and slightly warm; temperature in axilla 99.3°; pulse weak, 88; tongue brown and dry; no cramps, but great abdominal tenderness; great thirst; urine suppressed. 4 p.m.: Has passed water freely, of a deep amber color; specific gravity 1020, acid, containing no albumen; tem-

perature in axilla 100°; pulse stronger, but easily compressible, 92. No return of vomiting; passed a bilious motion. He appeared much better the following day, the choleraic symptoms not returning; but abdominal tenderness persisted. The tongue was at times dry and furred. A bilious mucous diarrhoea, occasionally containing specks of blood, set in; the pulse remained somewhat above the normal, and was hard and small; the temperature in the axilla varied from 99.3° to 100°.—11th, 7 a.m.: Passed a restless night. Had three motions during the day, and two at night. The dejecta are semi-liquid, scanty, bilious, containing some mucus, but no blood. Complaints of pain in the abdomen, which is increased by deep pressure, whilst a moderate pressure is not complained of. No relish for food. Temperature in the axilla 98.2°; pulse soft and small, 92. 4 p.m.: Towards 11 a.m. a slight exacerbation set in. Temperature at the time of report 100°; pulse 104. The two following days his condition remained very much the same. Towards the evening of the 13th he had a return of the choleraic symptom, but blended with those of the severe abdominal lesion from which he was suffering. At 7.30 a.m. on Dec. 13th we read in the notes of the case: "Had one copious evacuation just now, very offensive, of a dark-brick color, evidently containing much blood intimately mixed with the discharge; a little mucus floats over it; the pulse cannot be felt at the wrist; the countenance is anxious; the face pinched; eyes sunken; voice weak; tongue cold at the tip; extremities cold; no cramps; respiration hurried; temperature in axilla 98°. At 9 p.m. a slight reaction took place, leaving the pulse very weak and small; the urine still suppressed."—14th, 7 a.m.: Passed a copious dark-red motion, similar to that of the day before, but even more offensive; abdomen slightly distended, and very painful even on slight pressure. Temperature in axilla 98°; pulse very weak, 92. The eyes are sunken; the extremities cold; he is perfectly sensible, and complains of abdominal pain. Died at 3 p.m.—Treatment: During the stage of collapse the treatment was the same as in the other cases. On the disappearance of the choleraic symptom, quinine both by the mouth and hypodermically was freely given as in the former cases. Against the abdominal symptoms the following treatment was adopted: Fomentations; small doses of castor oil, with tincture of opium; Dover's powder at bedtime; seven parts of belladonna liniment to one of chloroform liniment applied to the abdomen on spongio-piline, cold water enema, etc. The diet consisted of milk and yolk of eggs; a little arrow-root or sago in beef-tea; brandy was given with eggs during the last few days.

Necropsy, fifteen hours after death.—Weather cool. Rigor mortis fully developed. Head: On opening the skull the large vessels are seen distended by a pinkish serous fluid, whilst the capillary vessels are well defined and of a dark-black color. Brain: The grey substance is of a pale-rose color superiorly; of a slatish tint, getting darker towards the inferior part of the brain. White substance of a rose color; some serosity escapes on section; many of the puncta vasculosa are of a dark color, like small grains of powder, more numerous and darker towards the centre of the brain; they are well marked on the floor of the lateral ventricle. These are with difficulty removed by gentle friction with the knife; under the microscope they seem to consist mostly of an irregular, sharply defined, granular substance. The left ventricle contains about a drachm of clear serum, the right somewhat less. Chest: The external appearance of the lungs is very remarkable, being covered

with extensive dark-black patches and lines; the base and inferior margin of the lungs are almost uniformly black; the lungs are orepitant; some engorgement exists in the inferior lobes posteriorly, and more marked in the left lung. Heart healthy, small; a small soft black clot is found in the right auricle. Abdomen: The abdomen is considerably distended; on opening the cavity, the omentum is seen rolled up and of a dark-brown color; the peritoneum contains no fluid nor any signs of recent inflammation, except around the omentum; the large intestine is considerably distended and of a dark-slate color; in parts this dark coloration is intense. On examining the large intestine the mucous membrane is found in many places to be the seat of small deep ulcers, looking as if punched out; the largest are about half an inch in diameter. These ulcers are surrounded by a circle of fine black lines formed by capillary vessels distended by a black substance which under the microscope appears to consist almost entirely of black granular matter. Several of these ulcerations extend to the serous layer. In the transverse colon several of the ulcers have perforated the bowel, which is only protected by the omentum adhering intimately to it by a thick layer of plastic lymph. On separating this layer with great care, the transverse colon is seen to be cribbled with numerous small rounded perforating ulcers, all presenting around them the peculiar ring of closely packed and beautifully defined dark minute capillary vessels. The appearance of the small intestine is normal, except some patches here and there of a darker hue; no ulcerations are found in it. The stomach also presents some patches of a darkish color, but is the seat of no ulceration; its mucous membrane is easily torn, and appears swollen. Liver: Weight 3 lb. 4 oz. Posteriorly towards the base, and at the extremity of the right lobe, it is of a dark-brown color, but only superficially; with this exception the appearance of the liver is normal. On section it appears moist, and gives issue to a certain quantity of serous fluid, and by pressure this fluid is readily obtained. The gall-bladder contains a couple of ounces of dark-brown bile, thick and ropy; abundant flakes of cholesterine are found suspended in it, adhering to thick mucus. Spleen: Weight 14 oz., small; the capsule is shrivelled, and apparently of normal consistence and coloration. Kidneys: The cortical substance is of a dark-slate color, more marked in the left kidney, where the appearance is remarkable; otherwise healthy. Some blood taken from the mesenteric veins and examined under the microscope reveals the presence of free granular pigment, some contained in what appears to be large hyaline cells.

All medical men residing in India have but too often occasion of attending cases of cholera; nevertheless, when I witnessed my first case of malarious cholera, I remained awhile under the impression that I had to deal with a case of real cholera. No symptom appeared to be wanting. Vomiting, purging, anxiety, rapid breathing, loss of voice, pulse weak or imperceptible, skin shrivelled, eyes sunken, cramps, coldness of the surface, etc., all the symptoms characteristic of cholera, were present. Still there are differences, and these are of great importance as assisting us in diagnosing between the two diseases. In malarious cholera the vomiting and purging are less frequent, less distressing, and these symptoms cease at an early date. The alvine discharges contain generally some bile, or are tinged with blood, or are like dirty water, or almost clear, but never presenting the whitish appearance so well known as rice-water stools. The cramps in the cases I have observed have been limited to the abdominal muscles and

lower extremities. A third point of great moment is the rapid reaction, or rather the almost total absence of reaction, the patient passing from a state of deep collapse to one of convalescence in the space of a few hours, and with a return of all the choleraic symptoms should the following paroxysm not be checked. The influence of treatment is also well marked. In India we are well aware of the danger of administering stimulants and opium during the collapse stage of cholera; in the sideration produced by malarious poisoning these two remedies are indicated and are followed by the best results. Again, the value of quinine points to the intimate nature of the disease; in five cases out of six this drug acted favorably, and no return of the dangerous paroxysm took place. The fatal case afforded us an insight into the pathology of the disease, and nowhere are the differences and distinction between the two forms of cholera better marked and ascertained. In malarious cholera post-mortem reveals a condition of intense melanæmia; a separation of the blood pigment, the blocking up of the capillaries by this altered substance, the presence of a rose-colored serous fluid in some of the large bloodvessels, and of a dark thick fluid in others.

In malarious cholera, if we take the fatal case here recorded as a guide, we find that the morbid action acts with greater intensity on the circulation of the alimentary canal, the stasis of pigment in the capillary circulation of the large intestine producing partial necrosis of the intestinal coats, manifest in this case by numerous small deep ulcers in the ascending and transverse colon, surrounded by a perfect ring of obliterated capillary vessels. In another case of pernicious fever which ended fatally, and which was entered under the name of "congestive," the localization of the disease did not exist as in this case of malarious cholera, while the symptoms during life were those of congestion of all-important organs, not limited to the digestive tube. As a comparison I extract the following from the notes of the post-mortem examination of the cases just mentioned: "The grey substance of the brain is of a dark-brown color; the white substance is dirty-looking and cribbled, with black spots. Externally the lungs are quite black, only here and there a few spots are of a normal color. On section this dark coloration is seen to permeate the lungs almost completely. The muscular tissue of the heart is of a uniform brown color. The inferior margin of the liver is intensely black, its superior aspect being dotted with black spots. The gall-bladder contains some two ounces of dark-black bile, ropy and full of cholesterine scales. The spleen is small, of a dark-slate color, and having a fleshy appearance. The large intestine is here and there deeply injected, showing dark circular rings, but no ulcerations; the mucous membrane is somewhat swollen in the centre of the rings. The kidneys are of a dark-slate color. The vessels of the brain and of the internal organs are distended by dark-black thick blood; superficial blood-vessels empty, or containing pale rose-colored serum." In malarious cholera, melanæmia, the result of intense malarious poisoning, is doubtless the primary and essential cause of this peculiar disease; the collapse, the disordered condition of the circulation, and of the digestive organs are due to the altered condition of the blood and to the obliteration of the large capillary circulation of the intestinal canal by modified blood pigment.

I wish to call attention to the condition of the spleen. In the fatal case it was found shrivelled, but apparently of normal consistence and coloration. In all cases of pernicious and remittent fevers examined after death I have found the

spleen almost normal in size, although not necessarily healthy. I believe that the alleged constant increase of volume of this organ in malarious fever is an error, and that the pathological condition of the spleen in certain forms of malarious fevers requires further investigation. According to the observation I have been able to make, it appears to me that enlarged spleens are more generally found among the inhabitants of certain malarious localities than of others, and as a rule this condition shows itself when malarious fever has been contracted after drinking water obtained in malarious localities. For instance, the inhabitants of the Gheer, a forest district in the province of Kattiawar, contracted rapidly enormous spleens after a few paroxysms of fever only; and it is a fact well known to travellers in that district that a residence in the Gheer is not followed by fever if the precaution be taken of carrying a supply of drinking water whilst crossing or dwelling in that forest. Large spleens are also met with when the cold stage of intermittent fever is intense and prolonged. Among the 1,756 cases of malarious fever which I have attended during the past ten months, I have generally found this to be the case, and I now look upon a moderately enlarged spleen as a favorable symptom, having seldom met with this condition in the 93 cases of remittent fever or in the 10 of pernicious fever treated during that period.

OCCASIONAL RECORDS IN THE SCIENCE AND PRACTICE OF SURGERY.

By OLIVER PEMBERTON, F.R.C.S. Eng.,

Senior Surgeon, Birmingham General Hospital, and Professor of Surgery in Queen's College.

LOOSE BODIES IN THE KNEE-JOINT.

It must be accepted that our knowledge of the exact mode in which "loose bodies" form in joints is, to say the least, at this day uncertain. Practically our experience arises only from what happens in the knee; for although met with occasionally in the elbow and even the hip, they so seldom call for interference, and are comparatively so unimportant, that further reference to their presence elsewhere than the knee is unnecessary. That their origin in early adult life is in the main traumatic, I for my own part entertain little doubt. The pursuit of football may be fairly charged with establishing abundant proofs as to this. Thus, a few years since, I saw a gentleman of much muscular power, who, previously to encountering the struggle of the game on a given day, had sustained no injury to or had had any disorder of the knee whatever. He had fallen during the fight, and being unable to rise was carried off the field, and I was called to see him a few hours after the occurrence. When I examined the knee I found a con-

Tabular Statement, showing the Weight, Appearance and Condition of the Spleen in Malarious Affections.

<i>Name of Disease.</i>	<i>Weight of Spleen.</i>	<i>Appearance and Condition of Spleen.</i>
1. Remittent fever.....	14 oz.	Normal on section.
2. " ".....	8 oz.	Small, shrivelled, normal.
3. " ".....	12 oz.	Shrivelled; hard, dark-brown color; cuts like the liver.
4. " ".....	12 oz.	Normal.
5. " ".....	9 oz.	Shrivelled, rather firmer than normal.
6. " ".....	16 oz.	Capsule shrivelled, moderately firm, deep brown color.
7. Remittent fever and melanæmia.....	21 oz.	Dark color towards convex surface, elsewhere of a light-brown color, fleshy, hard and resistant; contains dark-black blood.
8. Remittent fever and melanæmia (chronic case).....	2½ oz.	Shrivelled; looks like a piece of raw muscle; firm; no splenic mud.
9. Malarious dysentery.....	6 oz.	Normal.
10. " ".....	7 oz.	Carnified; no splenic mud; of rich brown color.
11. Pernicious fever (congestive).....	10 oz.	Dark-slate color, gorged with black blood; easily torn.
12. " " ".....	7 oz.	Small, very soft; contains black blood.

In Cases 1, 6, and 7 there is a previous history of repeated attacks of quotidian intermittent fever, and the slightly enlarged spleen existed in that condition previous to the fatal illness. On the other hand, the peculiar condition of the bile in cases where melanæmia, even in a slight degree, is present, is very characteristic. Generally the gall-bladder is somewhat distended, and contains from two to three ounces of dark-black bile, very thick, ropy, full of small bright scales of cholesterine, and gives a slight acid reaction. This condition was well marked in the fatal case of malarious cholera, in two of the congestive forms of pernicious fever, and in cases of remittent fevers, where the fatal course was rapid.

Poona.

—In the Canadian Dominion and Provincial Houses at present in session there are sixty members of the medical profession, a representation of about 2 per cent. Half of these are in the Dominion Parliament, seven in the Senate, and twenty-three in the House of Commons. Nearly all represent constituencies of the maritime provinces. Eight possess English, twelve American, and the remainder Canadian qualifications.

siderable effusion had taken place within the joint, so as to render any exact judgment as to what had happened impossible. The effusion subsided with rest and he was able to walk; but in a few weeks came to me and said something moved in and outside the joint and had nearly thrown him down once or twice in walking. On examination I readily detected a movable body, about as large as an almond, situated just above the level of the patella on the inner side. I pointed out to him the desirability of removal, but he preferred a supporting case and I saw no more of him. After forty years of age the rheumatic diathesis exercises a chief influence in the production of the "loose body" leading to that typical calcification seen so frequently in the joint structures of aged rheumatic people. Assuredly my own experience leads me to the conclusion that injury is the chief factor in causing a chipping or breaking off of the joint surface, and that as time goes on the loose body thus produced is found to present appearances according to its age and, as it were, to the extent of the wear and tear in movement it has undergone: at one time being cartilaginous or fibrous, or osseous or mixed, as the case may be, the ultimate shaping and structure of the body being doubtless greatly influenced by the predominance of the rheumatic habit.

Those curious in the investigations as to other and widely different modes of origin, would do well to refer to the ninth chapter in Mr. Barwell's treatise on diseases of the joints, and it must never be forgotten that Hunter's view as to the changes that blood effusions may assume, and so develop into these bodies, has always been regarded as a practical solution of the origin of many, and it certainly, in my judgment, adds great weight to a belief in the doctrine of a traumatic origin for the greatest number. The inquiries of Poncet, based on histological considerations, whilst admitting a traumatic origin for these "arthrophytes," strive to establish a distinction between these and those that have once been pedicled or attached, to the effect that the true traumatic ones never show any remains of a hilus or of any pedicle. I am unable myself to add to the value of these observations, but the subject of such a distinction is filled with interest for future verification.

CASE. *Long-standing Loose Body in Knee; Operation for removal; Treatment of Wound by Lister's Dressing; Recovery without Suppuration.*—J. L., aged fifty-five, a railway guard, was admitted into hospital on Nov. 10th, 1880, on account of pain and swelling in the right knee. The patient was a strong, healthy-looking man. He stated that he had never injured the joint, nor had he been laid up with gout or rheumatism. For some time the knee had been giving way, feeling less strong, being occasionally swollen, and on and off for twenty years he had been aware of the presence of a movable body, which occasionally absolutely prevented the use of the limb. On examination

Fig. 1.

Concave surface, lined by thin yellow covering, terminating all round in an elevated irregular margin, lightly and delicately fretted like a lace edging, and having the hardness and appearance of very white bone.

the joint was seen to be larger than natural, due evidently to an increase in synovial fluid. There was no thickening, and no pain, save in movement. On the outer side, between the patella and the condyle, was felt, resting, a large substance, oblong in shape, irregular, thick, and freely movable. He thought that another, and smaller, substance had shifted about on occasions, but that the one described, and which alone presented at that moment, was the cause of all his trouble. On the 24th, "rendered safe by Listerism," I made an incision directly over the body, of two inches and a half long, opening the synovial bag to the same extent. Extrusion was not immediate, as in some cases, by expulsion, owing to the fringed edges of the body catching the lining-membrane. To overcome this the handle of the scalpel was needed to turn it edgewise, when it readily slipped out. Synovia to the extent of a few drachms flowed through the wound, which was at once closely

sutured without the insertion of a drainage-tube. In the after-progress the wound healed by the first intention without suppuration, there being no rise in temperature and no constitutional disturbance of any kind. All dressings were discontinued in fourteen days, and he left the hospital, wearing his support, on Dec. 24th. I saw and examined him on the 4th inst. He was well in health, and moving about with a hinged case as guard at a level crossing. The affected knee was but a little larger than its fellow.

Fig. 2.

Convex surface, of the same appearance uniformly as the margin in Fig. 1, but fretted all over, and without any yellow lining.

To Professor Tilden, F.R.S., and Professor Haycraft, of Mason's College, I am indebted for a chemical and microscopical examination.

Prof. Tilden reports:—"Weight of the whole nearly 99 grains. It yields 65.3 per cent. of white ash, consisting of carbonate and phosphate of lime."

Professor Haycraft:—"The part examined consisted entirely of cartilage. This was not unlike the calcified rib of an aged person, the matrix of the cartilage being (especially near the cells) filled with ossified fibres. It is surrounded by a membrane which is clearly fibrillated, and of distinct thickness, but containing no stainable cells. It is probably a membrane of lymph which has deposited on the cartilage. Its thickness is about 1/300 of an inch on an average."

There remains but to remark on the peculiar shaping of this body, the like of which I have not previously experienced. The need of the insertion of a drainage-tube for the first twenty-four hours must be determined by the amount of fluid in the synovial bag, and by the chance of blood passing in from the wound. As a rule a drainage-tube is advisable. Lastly, I ask, after six and thirty years' dealing with surgery of all kinds, what confidence should I have had in opening this man's joint at fifty-five years of age without danger to life or limb, but for that system of dressing the wound for which we are indebted to Joseph Lister?

Birmingham.

ON THE FORCED FEEDING OF CHILDREN.

By J. SCOTT BATTAMS, M.R.C.S.,

Resident Medical Officer, East London Hospital for Children, Shadwell.

I VENTURE to offer a few practical remarks on the above subject because this method of introducing food and remedies into the stomach has a very distinct value in a variety of conditions. It is, I believe, too little used both in adults and children. My own short experience being chiefly limited to children, I have not touched on the subject as it

affects adults. We have in adults the rectum and lower bowel as an alternative route for introducing food, and their great power of absorption, especially of peptonized food, is well proved. The ease with which nutrient enemata are given and the little irritation they cause, when properly prepared and administered, will always make rectum feeding popular, even in cases where some other method might with advantage be substituted. In children, on the other hand, whatever absorptive power may be possessed by their lower bowel is more than counterbalanced by their greater reflex excitability. It is almost impossible to continue nutrient enemata for many days; they reject them, however constituted or introduced. And both in adults and children food absorbed from the lower bowel can never long be substituted for food that has undergone the natural digestive processes. Of course, I exclude cases where the stomach is not available. I would not be thought to advocate or justify a resort to any artificial means when it is possible, by a combination of tact, kindness, and firmness, to introduce a sufficiency of food by the natural method and route. Those whose experience in treating children is largest will know best how difficult or impossible the task often becomes. The remarks lately made in *THE LANCET* concerning forced feeding in lunatic asylums will never, I trust, have to be made in the case of children's hospitals. Children may very rarely seem obstinate as lunatics in the matter of food; but their obstinacy nearly always has its origin in physical, and not mental, conditions. Refusal to take a sufficiency of food from sheer obstinacy must, I think, be very rare. To use any method of forced feeding in such a case would generally indicate want of judgment on the part of the surgeon, and an absence in the nurse of most essential qualifications. The methods of feeding I advocate can barely be called "forced." In any large children's hospital, however skilled the nurses, and however numerous in proportion to patients, there will always occur cases where some such method of feeding is plainly indicated.

I pass on now to consider the various methods of forced feeding at our disposal, briefly mentioning their several advantages and disadvantages, and indicating the class of cases in which each method finds its special application. Finally, I shall venture to enumerate some of the conditions in which forced feeding might possibly become a more or less valuable resource.

Methods of Forced Feeding.—Under this head I have nothing original to advocate. The methods are fairly well known, I believe, even though not as frequently and intelligently used as they might be.

1. *Œsophageal Tube by Mouth.*—This is the method I least advocate. It is not as generally useful as, and is, as a rule, more difficult to apply than, any other method. In any plan of forced feeding one cannot expect much co-operation from a young child. The most patient and experienced know how difficult it often is to get a glimpse of a child's throat even. Now, their power to resist in this method is greater than any other; and what with violent struggles, spitting, and attempts to bite the operation is not easy, and it leaves the patient distressed and exhausted. Moreover, it is in diseased conditions of the mouth and throat that forced feeding is often most usefully employed, and no less important is it to avoid the irritation caused by frequent manipulation. There are, of course, cases where it is easy and safe to feed this way. In such cases indiarubber or French catheters are probably the best Œsophageal tubes to use.

2. *Nasal feeding.*—(a) By pouring food down the

nostril. (b) By nasal tube carried to the back of the pharynx. (c) By a tube passed through the nose into the Œsophagus or stomach. The first and second methods require that the several links in the chain of reflex mechanism for deglutition shall be intact. If this be so, then when fluids are allowed to flow along the floor of the nose to the pharynx involuntary acts of deglutition occur. In applying the first method, the child should be in the recumbent posture and the head held firmly, if necessary. For administering the food I generally use a glass syringe or indiarubber enema bottle. About an inch or more of drain-tube should be slipped over the nozzle of the syringe, and the tube should be placed only just inside the nostril. The food should be slowly injected, allowing regular intervals for breathing. Sometimes the child succeeds in spluttering some of the food from the mouth or ejecting it from the nostril. This may be owing to the too rapid administration of the food. Should this not be the cause then by closing the other nostril or the mouth for a moment the child will probably swallow, being "out of breath." A funnel with a piece of indiarubber tube attached would also answer the purpose. I always strive to use the simplest materials and those most commonly to hand. Warm fluids are less irritating than cold. If medicines of an irritating nature are also given they should be well diluted. I have not found that bland fluids such as milk or milk and egg cause anything but the slightest irritation either in myself or in children. "Watering at the eyes" sometimes occurs. If for any reason we do not wish the fluid to be injected to come in contact with the Schneiderian membrane, then we could use the second method; here a soft tube is passed through the nostril as far as the back of the pharynx before injecting.

The first method of forced feeding as far as my experience goes is the best in the largest number of cases. It causes a minimum of irritation, and an obstinate child finding it cannot resist these reflex acts of deglutition, often ceases all attempts to do so. It is the simplest method also, and has the fewest attendant risks. And the fact that it does not excite any great resistance in the child is a great recommendation. I had lately to perform tracheotomy on a strongly-built child of three years, comatose as much from diphtheritic as from carbonic acid poisoning. After the operation no pulse returned to the wrist and his color did not improve. On attempting to give him hot brandy and milk he clenched his teeth and would have struggled violently. On giving it through the nose he swallowed without resistance.

The third method is one I have had occasion to use rather frequently. It is chiefly indicated in cases where food passes into the glottis, or where the necessary conditions for deglutition are imperfect or abolished. It is not so easy to apply as the first method, and causes more irritation. The mucous membrane of the nose, though very tolerant of fluids, is not so accommodating towards anything solid. But in many cases in which I have used it sensibility has been blunted or abolished. On the other hand, even when this has not been the case, I have fed in this manner for days and weeks together with very little evidence of discomfort from the child, and with no apparent local damage. A case is on record in which an adult for stricture of Œsophagus wore a tube passed through the nostril for ten months. After many trials upon myself and others I find a vulcanized indiarubber catheter the easiest to pass, and the one which causes least irritation. The catheters I have always used bear the name of "Jacques" as patentee; they are extremely well

made and stiff enough not to kink. In young children a No. 7 is probably the most useful size. I generally inject the food by means of a glass syringe or indiarubber enema bottle. But as the end of the catheter is not easily slipped over the nozzle of the syringe, I unscrew the nozzle of an ordinary brass dressing syringe, slip the end of the catheter over its tapering end, and over its screw end place a piece of drain tube of sufficient size to admit the nozzle of the syringe. The catheter should be well oiled or smeared with vaseline before passing it into the nostril. It should be passed by slight pushing movements to the back of the pharynx, where it often causes some slight retching. As the tube passes down the œsophagus to the stomach, these signs of irritation cease. It is known to be taking the proper course by the slight amount of obstruction met with, and also by the length of tube passed. When the stomach is reached air and liquid food are often forced out at the end of the catheter. It is often more easily passed through one nostril than the other, and the erect posture is sometimes more favorable to its passage than the recumbent. When the catheter has entered the œsophagus or stomach, and signs of irritation have passed, the food should be injected slowly, taking care not to introduce air. On withdrawing the catheter, which should be done rapidly, it is important to pinch the end, so that no fluid may trickle into the glottis and cause cough and possible vomiting. The catheter is more likely to pass into the mouth than the larynx, and then, besides the sensation of obstruction, the child retches a good deal and soon opens its mouth, and the tube may be seen curled up. Cough and retching favor its passage into the mouth. The catheter seldom finds its way into the larynx; should it do so, cough and dyspnoea are excited, and even if these signs were absent the length of tube passed would be a fairly certain indication as to whether the catheter had passed into the larynx and trachea. When the tube is passing easily down the œsophagus, the whole length may be played out without any sensation of resistance. On the other hand, should the catheter pass into the larynx, it soon meets with obstruction before even half of it has passed.

This last method of feeding—viz., by a catheter passed through the nose into the stomach—is exceedingly useful in cases of tracheotomy for diphtheria, in which a few days after the operation food enters the larynx, and is coughed up by the wound. Whatever the etiology of this condition may be, it is, I think, quite distinct from diphtheritic paralysis, though I have seen a case in which it was followed after an interval of three weeks by such paralysis.

Out of twenty-five children on whom I performed tracheotomy, three had this complication. They were fed in this manner, one for nearly a month, another for three weeks, and one for a week; the last only recovered. Such a condition is generally transitory, and feeding by pulped or thickened food suffices. Where it persists, forced feeding by some method is obviously the only way to prolong or save life. In such cases in my experience there is considerable prostration, often a great tendency to diarrhoea and vomiting, and the wound shows little inclination to heal. There is therefore the greater need not only for food and stimulants, but also for remedies. Much gentleness in passing the tube and judgment in the matter of food are required in such cases. The tube is especially apt to pass into the larynx, and is seen through the wound. In two of my cases "watering" at the mouth occurred when the tube had reached the stomach; and in one child the saliva was swallowed, passed into the larynx, and

appeared at the wound. To avoid vomiting, the food should be bland, easily digested, and not too much in quantity. The children objected very little to this method of being fed, no local disturbance was caused, and the nurse passed the tube as easily as, or more so than, I did.

The conditions in which Forced Feeding may be useful.—I am unable to indicate very precisely all the conditions in which some method of forced feeding may be either optional, justifiable, or imperative. I can only say that in the East London Hospital, where children are admitted from birth to puberty, we have found more suitable cases than one might imagine. Take, for instance, a child with diphtheria in whom the throat and mouth are extensively implicated; such a child swallows with great pain and difficulty, and may even refuse to swallow, though great thirst be a concomitant symptom. The more or less routine treatment of such a case consists in the application to the throat at intervals of remedies more or less irritating. The child is also expected to swallow remedies that are at least unpleasant. The great importance of a due supply of food and stimulants is not lost sight of; hence the child is not only disturbed by the forced application of remedies, but at frequent intervals a minimum of food has also to be supplied. In such a case if I were compelled to adopt any routine plan of treatment, it would be something as follows:—The application to the throat, every two or three hours during the day, of glycerine and boracic acid, the brush being first moistened. This is not unpleasant, and the child soon allows it to be applied without much opposition. No harm comes from swallowing this application, and, as far as my experience goes, I prefer it to any other. As the local condition improves, the number of applications can be diminished. Then, as to food and stimulants, one must be apt in resource both as regards the quality and quantity of the former and not too fearful in one's administration of the latter. Should the difficulty of giving it be great, then I would feed by the nose. If medicines are given, then those I think should be chosen that can be administered with the food. Quinine, ammonia, and Fellow's syrup I have found generally well taken and retained in this manner. Quinine or liquid extract of bark in coffee and milk might also be tried. Large doses of iron and chloride of potash often cause vomiting. But in the presence of a grave disease the remedies for which are so numerous and diverse as to shake one's faith in any of them, one's trust, I think, should be mainly placed in a judicious administration of food and stimulants.

There are many other conditions in which we might be glad to avail ourselves of the nasal route to the stomach either for the administration of food or remedies. I have roughly enumerated some of them as follows:—

1. In conditions of the throat and mouth in which, either from mechanical causes or from great pain, it is difficult or impossible to administer food by the mouth—viz., in severe tonsillitis or ulceration; in anginose and malignant forms of scarlet fever; in severe cases of thrush and those horrible cases of cancrum oris; in injuries to the throat and mouth from corrosives and boiling water, or after injuries from violence or serious operations.

2. In convulsive and allied states this is the method by which we can administer both potent remedies and food. In uræmic convulsions I have once or twice given bromide of potassium by the nasal tube. In infantile convulsions, from whatever cause arising, we can thus quickly give an emetic, purge, chloral, or food. In tetanus and hydrophobia medicines and food can seldom be given

by the mouth, but when given per nares the patient has no control over the administration. In one case of trismus neonatorum I fed the child in this manner with its mother's milk every few hours for two days, giving chloral at the same time.

3. In cases of insensibility more or less pronounced. Thus in the later stages of tubercular meningitis, all hopeless though the case has then become, we may still prolong life a little by forced feeding. In cases of cerebral hæmorrhage or great shock, we might be glad under certain conditions to administer a diffusible stimulant and food. In any child where insensibility is sufficiently deep to abolish all reflex action, of course the tube should be passed into the stomach either by the nose or mouth. The passage of fluids into the glottis might under such conditions be instantly fatal.

4. In cases of narcotic or other poisoning in children I have only once had occasion to use the nasal route to the stomach. It is certainly no easy matter in the majority of cases of poisoning in adults to apply the stomach pump, on account of their struggles. And there would be the same difficulty in passing an œsophageal tube in some strong children, even though their resistance be more easily overcome. In such a case one might more easily pass a tube through the nose into the stomach, draw off by syphon action or by suction its fluid contents, wash out the stomach if necessary, and inject some antidote or remedy. One drawback to such a method would arise from the blocking of the tube by solids too large to pass. In some cases of poisoning, where emetics are indicated, they can be administered per nares, with a rapidity and certainty that are not always obtained when they are given by the mouth.

5. In cases of paralysis, as after diphtheria or from brain disease, where the child cannot swallow, the œsophageal tube is often the only way to administer food and avert starvation.

6. In cases marked by extreme prostration, as in enteric fever and typhus. In the "typhoid state," from whatever cause arising, there will sometimes occur a case in which the demand for food and stimulant is urgent, the difficulty of administering it is very great, and the necessity for not distressing the patient most important. During the late epidemic of typhoid, a girl of four years was under Dr. Donkin's care at the East London Hospital. High temperature and much diarrhoea were present, and her voice became hoarse soon after admission. She was a perfect fury in the violence of her resistance to all attempts to feed her, and the end was only attained as she became exhausted. During the last week of her life I fed her almost entirely by the nose with only the slightest show of resistance, though she still battled violently against attempts to feed her by the mouth. Urgent dyspnoea came on, and she dropped back dead just as I was about to perform tracheotomy. In infants in a state of collapse I have frequently used the tube either by the nose or mouth to inject stimulants or food. The spark of life is too feeble in such cases to run the risk of quenching it by fluids passing into the glottis. The number of infants admitted into this hospital too feeble to suck is very large. As a rule, spoon feeding is sufficient, only a very little food being given at a time, and that carried well to the pharynx. I have found a syringe, and a small piece of drain-tube used in the same manner very convenient. The food may also be trickled down the nostril as before described.

I may perhaps seem to over-estimate the importance of the subject on which I have written, and to underrate the difficulties attending the ap-

plication of the methods I have mentioned; but looking back through only a short experience I know I have seen many a child's life prolonged, and some lives, I honestly believe, saved by a timely resort to forced feeding. To add a few hours to the ebbing life of some poor child is no great achievement I know, but more than once I have thus been enabled to give the parents a chance of seeing the last of their little ones, a matter of no small moment in a children's hospital; and apart from all considerations for the friends and our own deep responsibility in the matter, it is thus we help to serve the highest and best interests of our hospitals. The silence of most of our standard authorities on the subject of forced feeding, and the fact that scores of practitioners during a long professional life have had no practical experience of it, seem sufficient excuse for my imperfect remarks.

Note.—The glass syringe with a piece of rubber tubing slipped over its nozzle is a very useful apparatus for administering food by the mouth. In the infant's ward in the East London Hospital there are always five or six children being fed by this means since I first introduced it. The sister of the ward, whose skill and devotion make her opinion valuable, says it is one of the simplest and most useful little devices for feeding the sick with which she is acquainted. After operation for harelip all our infants are now fed by this means. It may in many cases with advantage be substituted for the feeding-bottle, spoon, glass, feeding-cup, and other sick room utensils. The tube should be lightly placed between the lips and the fluid very slowly syringed into the mouth. With a syringe in each hand and two babies placed side by side, I have fed them in this manner simultaneously. It is equally useful in the case of adults. A patient can thus be fed without the least change in his position whatever that may be. Take, for instance, a heavy man prostrated by some painful illness; in such a case any movement may be as injurious to the patient as it is painful. What is the not uncommon process of feeding in such cases? A heavy, helpless patient is raised by some fragile nurse, with pain to the one and discomfort to both, to a more or less constrained position; beef-tea is presented to him in a feeding cup or open glass; he gulps down a portion, and the remainder probably runs over him; he falls back, thankful the operation is over, and neither party looks forward to its repetition with pleasure. Now, with a syringe and tube the same amount of fluid may be gently syringed into the patient's mouth without the least change of position on his part; he need not even trouble himself to suck. The child may feed the man; it becomes the very poetry of sick feeding.

ON REFRACTURE OF THE PATELLA.

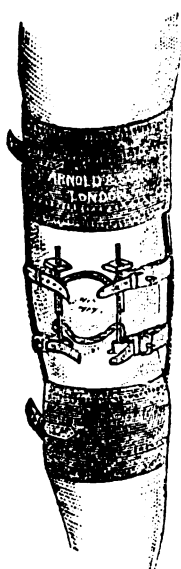

By H. PARSON, M.R.C.S., L.R.C.P. Ed.,

Assistant Medical Officer, Royal Surrey County Hospital.

PERHAPS the following particulars of a case of refracture of the patella, together with a description of the appliances used during the treatment may be of interest to some of your readers.

In December, 1874, Mr. — fractured his left patella at the junction of the upper and middle thirds. In October, 1880, he fractured the same bone at the junction of the middle and lower thirds; and in August, 1882, he refractured the left patella at the seat of the last injury—viz., at the junction of the middle and lower thirds. This last accident occurred August 6th whilst staying at Amsterdam. He was seen by a local surgeon who

applied suitable splints, and the patient started for England on August 8th, reaching his home on the 9th. I was called in on the 11th and found considerable swelling over the joint with about three-quarters of an inch of separation between the fragments; the amount of separation which existed directly after the accident I could not ascertain. The lower fragment was small and very movable. He was wearing a leather splint with side supports to which were strapped two semilunar soft leather pads. By drawing the pads together and fastening them I got the fragments into close apposition, and the patient continued to wear this contrivance until the primary inflammation had subsided. I then devised the appliance of which an illustration is here given, and which is manufactured by Messrs. Arnold & Sons of West Smithfield. It consists of two semilunar pieces

made of some round, narrow, unyielding material, shaped to fit the edges of the lower and upper fragments. One piece slides on the other and admits of closing and separating them by means of screws and without any other movement; so that, when adjusted and firmly strapped to the side supports of a suitable splint prepared for it, the upper and lower pieces are perfectly rigid one with the other. It is then almost impossible for the patella to slip out of position. The semilunar pieces being narrow, they form grooves for themselves behind the fragments, and have a tendency to run under the bone instead of over-riding as most other appliances do; thus the pieces are kept firmly in good position in their proper plane and have no tendency to tilt. This apparatus was applied about the end of the third week from the date of the accident, and the patient removed to the couch.

At the end of the fourth week he came down stairs with assistance, and went out in a Bath chair. At the fifth week he walked round the garden with the aid of sticks. At the seventh week he walked a mile with one stick. At the end of the eighth week he returned to business, walking to and fro, that is, two miles daily. He could walk well wearing the appliance, and experienced very little inconvenience, and to the best of my knowledge the fragments never slipped once during the twenty weeks that he wore the splint. The pressure was relieved at times by small tufts of cotton-wool, and by wearing an old splint at night, but during the latter part of the time nothing was worn at night, thus abrasions from continued pressure were avoided entirely.

The patient now walks well, and is not particular as to distance, but still wears a contrivance to support the knee-cap and limit the movements of the joint. The advantages claimed for the appliance are these:—

1. As soon as the primary inflammation has subsided and the apparatus firmly and properly adjusted, the patient can begin to move about, and in a short time follow his usual business pursuits.

2. The long confinement to bed is avoided; thus the patient retains his health and strength, and the condition is more favorable to the repair of tissues.

3. Easy adjustment of fragments and the keeping of them in good position, without fear of slipping when the patient is walking.

4. The slight movement of knee in walking prevents a stiff joint, and keeps up sufficient activity in the parts to complete the union.

Lastly, but not least, as far as the patient is concerned, the reduction of the "doctor's bill," as he will require much less attention.

I consider the case here mentioned to be a good test case for trying the merits of the invention; for if the surgeon can secure a good union in a refracture and under such adverse circumstances, surely the results will be far superior in the case of primary fracture.

Guildford.

THE THERAPEUTICAL DRINKING OF HOT WATER; ITS ORIGIN AND USE.

By EPHRAIM CUTTER, M.D. New York.

THE therapeutical drinking of water at a temperature of blood heat to 150° F. having become popular enough to call for an allusion to it in *THE LANCET*, as a valuable American contribution to medicine, and since it seems to be used at random from the directions of its distinguished introducer, I have thought that the origin and proper use of hot water should become history. The practice dates back to 1858, when Dr. James H. Salisbury, of this city, concluded a series of experiments on feeding animals to ascertain the relations of food as a cause and cure of disease. Besides swine, he experimented on men. These he took in companies of six healthy laborers, placed under military discipline, which he enforced himself. He also ate and drank as they did. The men were kept on single articles of food, coffee, and water. Among these articles were beans, beef, bread, chicken, crackers, fish, lobster, mutton, potatoes, rice, turkey, oatmeal. The blood, urine, and feces of the animals were carefully examined microscopically and chemically daily without any preconceived idea to develop, but simply to ascertain facts and develop ideas from those facts. In this manner he went through the whole range of food to show the permanent value when lived on exclusively and singly. Among other things, he found that the fermentations of food, and the products of these fermentations, were the chief primary factors in producing the diseases which arise from unhealthy alimentation. With the idea of removing these diseases by removing their causes, he employed hot water in order to wash out the saccharic, acetic, butyric, hydrosulphuric, and lactic acids, and sulphide-of-ammonium fermentation-vegetations (yeasts), from the stomach and intestines. At first he tried cold water on his men to remove these products of fermentation, but the cold water caused distress, pain, and colic, so he increased the temperature of the water. Lukewarm water made them sick at the stomach, and excited peristalsis upward. The temperature of the water was increased to hot—110° to 150°. This was well borne, and afforded a feeling of agreeable relief, which thousands since testify to. The hot water excites normal downward peristalsis of the alimentary canal, washes down the slime, yeast, and bile through its normal channels, washes out the liver and kidneys, and the bile is eliminated through the bowels, and not through the blood *via* the kidneys. It was some time before the proper times of administration, and proper number of ounces of hot water, and the proper number of ounces to be drunk at meals could be settled in order to obtain the best results.

These directions may be found published in connection with the Salisbury plans for the treatment of consumption, Bright's disease, diabetes, fibroids, sclerosis, and colloid diseases. At the risk of repetition, and for the sake of a more thorough understanding of the subject, these details will be plainly and simply given.

1. *Directions for using Hot Water according to the Salisbury Plans.*—The water must be hot, not cold or lukewarm. By hot water is meant a temperature of 110°–150° F., such as is commonly liked in the use of tea and coffee. This is to excite downward peristalsis of the alimentary canal. Cold water depresses, as it requires animal heat to bring it up to the temperature of the economy, and there is also a loss of nerve force in this proceeding. Lukewarm water excites upward peristalsis or vomiting, as is well known. In cases of diarrhoea the hotter the better. In cases of hæmorrhages the temperature should be at a blood heat. Ice water is disallowed in all cases, sick or well.

2. *Quantity of Hot Water at a Draught.*—Dr. Salisbury first began with one half pint of hot water, but he found it was not enough to wash out, nor to bear another test founded on the physiological fact that the urine of a healthy babe sucking at the breasts of a healthy mother, the best standard of health, stands at a sp. gr. varying from 1015 to 1020. The urine of the patient should be made to conform to this standard, and the daily use of the urinometer tells whether the patient drinks enough or too much hot water. For example, if the sp. gr. of the urine stands at 1030, more hot water should be drunk, unless there is a loss by sweating. On the other hand, should the sp. gr. fall to 1010, less hot water should be drunk. The quantity of hot water varies usually from half to one pint, or one pint and a half at one drinking. The urine to be tested should be the *urina sanguinis*, or that voided just after rising from bed in the morning, before any meals or drinks are taken. The quantity of urine voided in twenty-four hours should measure from forty-eight to sixty-four ounces. The amount will, of course, vary somewhat with the temperature of the atmosphere, exercise, sweating, etc., but the hot water must be given so as to keep the specific gravity to the infant's standard—to wit, 1015–1020. The urinometer will detect at once whether the proper amount of hot water has been drunk, no matter whether the patient is present or absent. Another test is that of odor. The urine should be devoid of the rank urinous smell so well known but indescribable. It should be like the babe's urine, free from odor, and deposit on cooling, and the color like that of champagne. The Salisbury plans aim for this in all cases, and when the patients are true and faithful the aim is realized.

3. *Times of taking Hot Water.*—One hour to two hours before each meal, and half an hour before retiring to bed. At first Dr. Salisbury tried the time of half an hour before meals, but this was apt to be followed by vomiting. One hour to two hours allows the hot water time enough to get out of the stomach before the food enters or sleep comes, and thus avoids vomiting. Four times a day gives an amount of hot water sufficient to bring the urine to the right specific gravity, quantity, color, odor, and freedom from deposit on cooling. If the patient leaves out one dose of hot water during an astronomical day, the omission will show in the increased specific gravity, as indicated by the urinometer, in the color etc. Should the patient be thirsty between meals, hot water can be taken any time between two hours after a meal and one hour before the next meal. This is to avoid diluting the food in the stomach with water.

4. *Mode of taking the Hot Water.*—In drinking the hot water it should be sipped, and not drunk so fast as to distend the stomach and make it feel uncomfortable. From fifteen to thirty minutes may be consumed during the drinking of the hot water.

5. *Length of Time to continue the Use of Hot Water.*—A period of six months is generally required to wash out the liver and intestines thoroughly. As it promotes health, the procedure can be practiced by people in health throughout life, and the benefits of cleanliness inside be enjoyed. The drag and friction on human existence from the effects of fermentation, foulness and indigestible food, when removed, give life a wonderful elasticity and buoyancy, like that of the babe above alluded to.

6. *Additions to Hot Water.*—In case it is desired to make it palatable, and medicate the hot water, aromatic spirits of ammonia, clover blossoms, ginger, lemon-juice, sage, salt, or sulphate of magnesia, are sometimes added. Where there are intense thirst and dryness, a pinch of chloride of calcium or nitrate of potash may be added to allay the thirst and leave a moistened film over the parched and dry mucous membrane surfaces. When there is diarrhoea, cinnamon, ginger, and pepper may be boiled in the hot water, and the quantity lessened. For constipation a teaspoonful of sulphate of magnesia, or half a teaspoonful of taraxacum, may be used in the hot water.

7. *Amount of Liquid to be drunk at a Meal.*—Not more than eight ounces. This is in order not to unduly dilute the gastric-juice or wash it out prematurely, and thus interfere with the digestive processes.

8. *The Effects of Drinking of Hot Water as indicated are:*—The improved feelings of the patient. The *fecæ* become black with bile washed down its normal channel. This blackness of *fecæ* lasts for more than six months, but the intolerable fetid odor of ordinary *fecæ* is abated, and the smell approximates the odor of the *fecæ* of healthy infants sucking at healthy breasts; and this shows that the ordinary nuisance of fetid *fecæ* is due to want of a proper washing out and cleansing of the alimentary canal from its fermenting contents. The urine is as clear as champagne, free from deposit on cooling, or odor, 1015 to 1020 sp. gr., like an infant's urine. The sweat starts freely after drinking, giving a true bath from the centre of the body to the periphery. The skin becomes healthy in feel and appearance. The digestion is correspondingly improved, and with this improvement comes a better working of the machine. All thirst and dry mucous membrane disappear in a few days, and a moist condition of the mucous membrane and skin takes place. Ice-water in hot weather is not craved; and those who have drunk ice-water freely are cured of the propensity. Inebriety has a deadly foe in this use of hot water.

9. *Summary of General Considerations on the Therapeutical Drinking of Hot Water.*—(a) Foundation for all treatment of chronic diseases. (b) Excites downwards peristalsis. (c) Relieves spasm or colic of the bowels by applying the relaxing influence of heat inside the alimentary canal, just as heat applied outside the abdomen relieves. (d) Dilutes theropy secretions of the whole body, and renders them less adhesive, sticky, and tenacious. (e) Inside bath. (f) Dissolves the abnormal crystalline substances that may be in the blood and urine. (g) Necessary to have the hot water out of the stomach before meals. (h) Its use is to wash down the bile, slime, yeast, and waste, and have the stomach fresh and clean for eating. (i) Promotes elimination everywhere. (j)

If objection is made, it must be remembered that we are 75 per cent. water. (c) The gas that sometimes eructates after drinking hot water is not formed by the hot water, but was present before, and the contractions of peristalsis eject it, or sometimes it is the air that is swallowed in sipping, as horses suck air. The amount of gas contained in the alimentary canal is larger than most are aware of, and yet it is not excessive, as it takes some time to eruct a gallon of gas from the stomach. This time can be tested by submerging a gallon jug filled with air under water and observing how long it will be in filling with water. (l) Some physicians have advised against hot water on the ground that it would burn the covering off the stomach. If this is so, then a denudation of the lining of the stomach for twenty-five years is compatible with a state of otherwise perfect health with no sign of illness for that period of time, and is also compatible with the numerous cures that have occurred under the use of hot water as a foundation during the past twenty-five years. Again, the same physicians drink tea and coffee at the same temperatures, and this act belies their warning and shows their inconstance and want of consideration before speaking. (m) These dicta about the therapeutical drinking of hot water were founded on physiological experiments at the outset, verified in pathology and based on the experience derived from the treatment of thousands of cases since 1858.

Personal Estimate of the Founder of this Practice.—"If I were confined to one means of medication I would take hot water." It may be added that he has drunk hot water for twenty-five years.

Corroboration of the Writer.—The writer testifies that his own personal experience and observation corroborate the truth of these statements of the Salisbury plans.

New York, 1883.

AUTOPSY ON A CASE OF PROLONGED VOMITING.

By H. WHEATLEY HART, M.R.C.S.

THE following case, recently under the care of Mr. Wm. H. Rix, surgeon to the Tunbridge Wells Infirmary, will, I think, be read with interest.

Mrs. E. J—, aged fifty-eight, had suffered more or less for twenty years from this distressing symptom, the characters of it being that frequently after food she suffered from a sense of pain and heaviness somewhat above the pit of the stomach, which continued until vomiting ensued. This, however, was not always so, as sometimes during a period of two or three days she would be tolerably free from both pain and sickness. On physical examination of both chest and abdomen, no signs had been discoverable; the urine contained no albumen, and the normal functions, except those of taking food and digestion, had been carried on well. The patient died on July 29th from gradually increasing anemia and inanition.

At the post-mortem the pleura were found firmly adherent throughout, but the lungs presented no signs of pressure; the pericardium was also intimately adherent where it met the chest-wall, and also to the whole of the surface of the heart; the left ventricle and aorta were considerably dilated; there were several bronchial glands much enlarged, and in a condition of calcareous degeneration. The mucous membrane of the stomach was fairly normal, with the exception of an area of undue vascularity along the lesser curvature; the organ itself was somewhat shrunken, while the cardiac

orifice was excessively contracted, only just admitting the little finger, and that with difficulty; there was, however, no thickened or indurated tissue around the contraction. The œsophagus was enormously dilated above this point of stricture, containing a large quantity of grumous fluid. It occupied a position to the right of the vertebral column, lying in the hollows formed by the angle of the ribs. At the spot where the dilated œsophagus came in contact with the diaphragm it was bent on itself nearly in the form of a right angle, forming a curve as it passed from the right side of the chest to the opening in the diaphragm on the further side of the mesial line. On removing the organ its shape was found to have a remarkable resemblance to an ordinary stomach; it had a gross cubical capacity of twenty-five fluid ounces, and the muscular tissue was found to be very much hypertrophied. The kidneys were slightly granular, but the other organs fairly normal.

The point of interest is that such a partial stricture should have caused so enormous a dilatation above it, and the strong probability is that it was due to the adhesions, existing in the thorax, undergoing gradual contraction, and so causing a deviation of the œsophagus from the direct line at its passage through the diaphragm, and thus was produced a dragging on this structure against the tendinous fibres of the diaphragm, converting a canal, the comfortable patency of which is so necessary to health, into a condition of obliquity and stenosis, varying according to the movements of the diaphragm and the contents of the thoracic cavity.

Tunbridge Wells.

DIPHTHERIA; ITS ETIOLOGY AND TREATMENT.¹

By ALFRED CARPENTER, M.D. Lond., etc.

THE etiology of diphtheria is still a disputed point. There are many reasons why this is to be regretted, the most important being that treatment must be empirical until its causation is determined with certainty. Intimately associated with causation are the sequelæ which follow upon its incidence, and no explanation will be satisfactory which does not thoroughly elucidate their occurrence. The latter may be divided into two sections: those which are immediate, and those which probably follow in the relation of cause and effect, but which are at present seldom associated in the minds of the medical attendant with the preceding diphtheritic condition. I propose to show the intimate relationship between these classes of cases, and to point out that treatment to be effectual must be based upon rational lines, and be followed out on those lines to the termination of the case. Without asserting that diphtheria and potato disease are in any way allied to each other, except by analogy, I have been struck by the similarity of the effect produced in both diseases. The breathing passages are impeded. There is a similar train of results, though in the opposite direction. In the one case carbonic acid cannot get into the plant to allow of the evolution of oxygen; and in the other oxygen fails to get admission to the blood-current, so as to allow of the oxidation of carbon in the various tissues of the body. There is in both cases suffocation and rapid death when the disease is immediately severe. If the course of the disease is not so rapid, and death does not arise from asphyxia, the nutritive fluid

¹ A paper read in the Health Section, British Medical Association, Liverpool, August 1st, 1883.

becomes altered by something intimately connected with the causation of the disease, and which leads to death either by paralysis or by failure of nerve power in the human body; whilst in vegetable life it arises from simple loss of power to assimilate the juices upon which the life of the plant depends. There is a blighted state produced by which the crop is destroyed sooner or later in the course of the season. If both these dangers are escaped, the fruit is permeated by a mycelium which produces seed of its own: the evil day is postponed; but when the store is opened in midwinter a large portion of the crop is found to be invaded by processes similar to necrosis, and which may be likened to the sequelæ of diphtheria. Even those potatoes which seem sound are permeated by mycelium, or have so-called resting spores in their buds only waiting for seasonable opportunities to develop into new growths, which will inevitably destroy the potato, and prevent any healthy production from that part of it which is so affected. The causation of one kind of potato rot is recognized as produced by a fungus called *botrytis*, or *peronospora infestans*, one of the genus *mucidines*, or *hyphomycetous fungi*. They form the commonest moulds upon decaying vegetable substances, and include some parasitic families which produce great destruction in vegetable matters. Their germs are always present almost everywhere, and only want a forcing bed in which they can develop, and then their effects are immediately manifest. There is great doubt in the minds of some men as to the capacity of parasitic life either to injure plants or animals which are in vigorous health. It is possible that this doubt has a sound basis, and that we may agree with my great teacher, John Simon, "that a contagium of a given disease, such as small-pox or measles [I here interpose diphtheria and potato rot] has no more power to influence the unprepared body than yeast has to ferment alcohol, or to turn pure water into beer." I am now inclined to think that this is so, and that in the absence of some impurity in the blood of the animal or the juice of the plant—that in the absence of some material which is the sequence of the act of living, and which material has not been properly excreted out of the system—the germs which set up parasitic diseases would fail to find a pabulum in which they could increase and multiply, and that they would be starved, so as to ultimately abort or dwindle away to nothing, and thus fail to establish a colony in their victim. I have taken up this view for a variety of reasons. It is true it is not indubitably established that infectious disease, such as diphtheria, is the result of filth in the home or in its surroundings, but the presence of the disease in the great majority of instances is intimately associated with decomposing excreta in some form or other. I have therefore come to the conclusion that when it fails to be proved to be so associated from the absence of any such visible cause outside the body, it is because the excreta have not passed away from the blood of the recipient, and that they are still within the curtilage of the human dwelling-house—that is, within the living precincts of its producers.

The connection of filth diseases with human excreta is a recognized fact. Diarrhœa, cholera, and enteric fever are certainly associated with human filth; a relaxed throat with diphtheritic exudation is also recognized as intimately connected with similar states, so that a person so affected cannot be cured whilst residing in a given dwelling house in which the air is impregnated with the results of sewage decomposition. He must move into a purer atmosphere before the diseased state of his mucous membrane can be remedied.

And why? He is like a man well able, under ordinary circumstances, to swim if naked; but his head is just under water because of heavy boots or other weight loading him beyond his swimming powers. The impure air acting like the boots, prevents that healthy assimilation of food by the aid of which he would recover power to resist the influence of the fungoid germs which irritate his mucous membrane; just as some men are from so-called peculiar idiosyncrasies unable to resist the influence of the pollen of some kind of grasses and become subject to hay fever, whilst others do not feel them in the least, and are not so affected.

I do not assume that the excreta of a human being retained within his own body are necessarily hurtful simply from retention. That is disproved every day of one's life, but I contend that it is impossible for an excretory organ to be defective for some time and to fail in its complete and regular duty without some minute particles of organic impurity being retained in the fluids of the body in a condition which is foreign to their ordinary state. The blood is placed in that form which is analogous to what obtains in the sufferer from hay fever, when a person so situated is exposed to the germs upon which diphtheria depends for its production, he becomes the victim of that disease. If he was not in that particular condition, he would not be affected by diphtheria any more than the majority of us in this room would be affected by hay fever if we joined a hay-making party. This view of the case will explain why we occasionally find diphtheria in exceptionally clean and healthy neighborhoods. It will explain its hereditary tendencies and the so-called idiosyncrasies of those who appear to be especially prone to its ravages. I have reason to believe that temperature has much to do with its sudden development. That whilst it is certain that ranges of hills in open country are liable to its incidence as much probably as less elevated spots, that it arises at clusters of cottages entirely away from sewers or a general water supply, and seems to arise *suo sponte*; yet it does at times follow lines of sewers in a way that shows that intimate connection with drainage which is suggestive of cause and effect; it is also propagated by milk-sellers, as is shown by evidence which cannot be disputed. It is not more prevalent in hot seasons, but, on the contrary, it seems more general in the colder months, producing greater mortality during or soon after sudden violent reductions of temperature than at other times. I have always found that its development has been associated either with washing-day, when hot water has been allowed to flow into the cesspool or drain, or that there has been a communication between the sewer and some steam-engine or other source of hot water, which has elevated the temperature of the sewerage to blood-heat. It is to this point that I wish to direct the attention of those who are inquiring into outbreaks of diphtheria. The connection of tub-night with croup is not unknown; I believe it was in Edinburgh that, some forty years ago, at a conference of medical men, it was discovered that Saturday night was the night upon which the majority of the attacks of so-called croup took place among the poor, and that it was shown to be intimately connected with the Saturday night tubbing with which the Scotch were then accustomed to treat their children, the steamy condition of the rooms in which they slept bringing into sudden activity the germs upon which I believe the disease to depend for its development. That a particular form of micrococci or germ is always present in diphtheritic exudation, and that this germ is capable of setting up the disease, have been established upon a sound basis. The germ has been

cultivated in the vitreous humor of the eyeball, it has passed through several generations, and the operator has ultimately been able to reproduce the same disease in another animal in a way which shows its complete identity. These micrococci are excessively minute, probably less than 1-30,000th of an inch in diameter. They have a life history of their own, and though not identical with botrytis or peronospora, they must have reproductive organs, they follow the life history of the algae, as well as being endowed with some of the properties of the fungal tribes, and have probably resting spores as well as ordinary spores, both kinds developing together. From analogy we may assume that the resting spores are much less destructible than the ordinary spores, and are capable of preservation under conditions which enable them to reproduce their kind whenever the conditions arise which are required for the purpose.

What are these conditions? (1) The presence of certain forms of excreta; (2) of an elevated temperature, not much below blood-heat, but below that requisite for the coagulation of albumen; (3) of an atmosphere saturated with moisture, and probably also with (4) an excess of carbonic or some other acid in the air, by which the growth of the germ is determined; and (5) some other meteorological or electric manifestation at present entirely unknown. If these states coincide, the resting spore becomes active, it finds material which it can assimilate, and the disease is set up, commencing in the mucous membrane of the throat, that being the very place in which we find moisture, warmth, and CO_2 . The way in which such actions do take place is manifest from the fact that the spores of a mushroom cannot be cultivated unless they have been in contact with the mucous membrane of some of the equine tribe. So diphtheritic germs (like the pollen of plants which fall upon the stigma of an appropriate carpel), as soon as they touch such a mucous surface, at once put forth all their vigor; an invisible mycelium is put out, a change takes place in the character of the fluids of the part, the disease arises and runs its course, and passes through the changes which indicate its presence. A felt-like mass forms in the throat, the patient dies asphyxiated, or the blood is so altered by the action of the micrococcus that the blood-corpuscles no longer perform their duty, and oxygen gradually ceases to be assimilated. This leads to failure of action in certain nerve centres, and paralysis may result. The micrococci have a life history of their own, a definite course to run; they are expelled by some of the excretory organs, and those which escape expulsion die in the course of time, leaving behind them spores similar to resting spores, which may set up sequelæ in an unexpected manner and at unexpected times. Returning to the conditions, let me say that as regards the character of the excreta this must be peculiar; that as scarlatina probably has its origin when apparently arising *suo sponte* in the blood of animals which are not in a healthy state, and which is undergoing decomposition, so the diphtheritic germ has its apparent origin *de novo* from morbid matter produced in the tissues of animals. It is probable that the excreta of vegetable feeders do not furnish germs which could develop into diphtheritic micrococci. That if a right condition be present the cells are hatched, and they then are capable of extension by so-called contagion, but that even then it is requisite that the recipient shall be in a state fitted to receive it, and like to the carpel of a fruit ready for the pollen which is peculiar to it, otherwise the cell fails to find fitting pabulum for its extension and the development of its reproductive organs. An elevated tem-

perature is necessary, together with an atmosphere saturated with moisture. I conclude that this is so, because I have always found the coincidence in first outbreaks, and the consensus of opinion points to the necessity for moisture or dampness whenever the disease is epidemic. I go also to analogy for support in this view. The potato disease spreads more rapidly in the damp atmosphere which is found among the rank vegetation of overgrown haulms on those days on which the sun is obscured by clouds and the air itself close, full of moisture, and the temperature high. Sunlight and dryness soon remove the incidence of potato blight. The latter, however, does not require the elevated temperature which is requisite for the hatching of diphtheritic spores, but the warmth of a day in which thunderstorms abound is sufficient for the purposes of promoting potato disease. That carbonic or some other gaseous acid must be present is probably the case, because it has been shown that minute fungi grow much more rapidly and much more luxuriantly in such an atmosphere. It is probable that water which is free from carbonic or some other acid in solution will not be able to propagate even typhoid germs for want of the necessary pabulum, which accounts for the fact of certain waters, apparently free from suspicion of the presence of any infective principle, suddenly developing such a tendency from having lost their power of neutralizing the CO_2 for want of lime sufficient for the purpose, or of discharging it into the atmosphere. In this case typhoid germs rapidly multiply in the water, and disease is spread by its means, and so it is that diphtheria suddenly springs into great activity. There is a rapid fall of temperature, lasting for a day or two; the managers in a given school, or other places similarly situated, are not prepared for the change; fires are not lighted, but the cold and usually damp air is shut out, and the atmosphere of the school becomes highly charged with CO_2 ; and if it should happen that a child with an infectious throat is present, the disease spreads as rapidly as potato rot spreads on a favorable day. If there are the excreta of such people in the sewer, the admission of large quantities of hot water forces out a steaming air into the closed-up premises from the defective drain. But how will this explain the sequelæ which so frequently follow upon diphtheritic mischief? I mentioned the fact that potato rot is known to be propagated by the agency of resting spores. These are spores or germs which are shut up in a very resistant envelope which enables them to retain their vitality in adverse circumstances, so that heat, if it be not much above 212° , and cold even at zero, will fail to destroy them. These spores may by analogy be fairly assumed to exist. The ordinary spores are evacuated from the system as the patient recovers, but the resting spores remain in contact with the lining membrane of the bloodvessels, or they are carried by the blood-current into some of those parts of the body which usually act as filters and retain matters which are foreign to the blood-current. Perhaps they attach themselves to lining membranes such as is on the valves of the heart; they may there as they develop set up actions such as ulcerative endocarditis, then being detached from the valves as they increase in size they irritate the membrane, and being carried on by the blood-current they produce emboli at the spot to which they are carried. There they multiply sooner or later, and the sequences of the disease appear as if they were separate and independent diseases, and as such are often registered among the causes of death, totally independent of the preceding diphtheritic condition.

I have the history of a considerable number of.

cases in which inflammations of different organs have come on a few weeks after the patient has suffered from a moderately slight throat affection which has not been recognized as diphtheria, but which has been coincident in point of time and place with true diphtheritic attacks, that I have been inclined to look upon the so-called inflammations as having been caused by diphtheritic emboli, and have treated them accordingly. That I now advise that course in the majority of cases in which the inflammatory attack appears to be idiopathic—that is, if it has not been preceded by some known chronic diseased state of the suffering part.

The treatment has been the use of ammonia as the proper stimulant, so as to reduce the acidity of the blood, for I have generally found these cases in constitutions which are either rheumatic with the lactic acid diathesis, or gouty with an excess of lithic acid in the constitution. I have generally given alkalies, as lithia or potass in combination with it, and when there has been an elevated temperature, which has indicated excessive chemical action in the invaded part, I have given the sulpho-carbolate of soda with the greatest possible benefit. This salt reduces temperature most likely by its antiparasitic power, for as soon as a few doses have been given the fever subsides, and the patient is much relieved; but if the medicine be left off too soon there is certain to be a relapse. This is very disappointing, and if the practitioner is disheartened and tries another remedy the patient will probably die; but if he continues the sulpho-carbolate he will ultimately destroy all the developing resting spores in the tissues of his patient, and lead him on to a perfect recovery. It is curious how in these cases organ after organ becomes involved in the disease; it is also curious, but highly satisfactory, that the congestions or embolisms follow one another in point of time, otherwise there would be very little chance for the patient to recover. I would urge the practitioner to continue the sulpho-carbolate in small doses, first with the ammonia, and after a time, with quinine, avoiding altogether the mineral acids, as such appear to allow of a more rapid development of resting spores and a further relapse. As regards the local treatment of diphtheria, I have been accustomed to treat it on scientific principles, and attack the disease just as my gardener attacks the oidium upon grapes and parasitic diseases upon vegetables generally. I apply the powder of washed sulphur to the throat very frequently, blowing it into the fauces, and applying it by means of a brush with a little glycerine or honey, alternating the application with a little sulphurous acid in solution. It is not a painful application, it destroys the mycelium and the ordinary spores which produce the disease; if this is done quickly, so that the growths do not penetrate to the deeper tissues, no resting spores will find admission to the body, and there will be no following sequelæ. I have also been accustomed to advise that creasote be kept in the room, so that the air may be placed in that condition which diminishes, if it does not destroy, the growth and development of hyphomycetous fungi.

— A LETTER has been sent to the Home Secretary by the Presidents of the College of Physicians and of the College of Surgeons, in obedience to a request made at a recent meeting of the Association for the Advancement of Medicine by Research, informing Sir William Harcourt of the almost unanimous feeling of the Fellows and Members of the two Colleges against the Bill for the Abolition of Vivisection.

LAPAROTOMY FOR INTERNAL STRANGULATION; WITH REMARKS ON THE OPERATION.

By BENNETT MAY, B.S., F.R.C.S.,

Surgeon to the Queen's Hospital, Demonstrator of Operative Surgery at Queen's College, Birmingham.

I HOPE that this record may be found to embody points of interest in the clinical history, diagnosis, and treatment of this form of intestinal obstruction, and may thus add another link to the chain of evidence which is rapidly accumulating on the subject.

On Saturday, Sept. 23rd, 1882, I saw Mrs. E— for the first time in consultation with her medical attendant, Dr. Jackson. She was forty-one years of age, the mother of four children, and furnished the following history. On the previous Monday morning, whilst dancing a little grandchild up and down by its hands, and necessarily straining somewhat in the act, she suddenly felt an acute pain in the lower part of the abdomen, became faint, and vomited the contents of the stomach. She had a small evacuation of the bowels the same evening, but it was quite limited to the contents of the lower intestine, and with that exception nothing either fecal or gaseous had since passed. Everything taken into the stomach had been rejected, though sometimes she enjoyed an interval of eight or ten hours without sickness. She had an anxious, pained expression, but there was no shock or symptom of peritonitis; pulse 90, full and strong; tongue furred and creamy; abdomen was distended and tympanitic, but not painfully tense, and no tumour or marked inequality could be found in it. Pain, which was never absent, recurred in frequent paroxysms, specially referred to the left of the umbilicus. As she said, pressing the spot with her hand, nothing could pass there; she wanted something moved from there. Vomiting was taking place in large quantities, but at long intervals, the vomited matters being intestinal, but not fecal in odor. Further inquiry elicited that she had suffered from pain after food and constipation for several years; she was subject to flatulent dyspepsia, pain in the abdomen, and at times experienced great difficulty in getting an action of the bowels. Her daughter said that at these times she would remain as long as half an hour at stool, returning from it quite ill and faint. It was positively established, however, that within twenty-four hours of the seizure she was quite well and passed a well-formed motion. The urine was being secreted in greatly diminished quantity. On the 21st she was seen by a physician, who prescribed morphia subcutaneously with ice, and indicated the probable need of an operation. This treatment gave considerable relief, and calmed both pain and sickness.

On the 24th the patient's condition was much the same as on the previous day, but the vomit was slightly fecal. To the left of the umbilicus an inflated intestinal coil caused the abdomen to look more prominent at that spot than elsewhere, but there was no tumour or dullness. The patient being under the influence of ether, I explored the rectum, and my first impression was that the obstruction might lie there, for the finger appeared to enter a cul-de-sac and on withdrawal was smeared with bloody mucus. However, after injecting a pint of warm water all feeling of obstruction had disappeared, and it was shown that the blood and mucus were due to piles, from which she suffered. She retained in all three pints of fluid, which shortly regurgitated unchanged.

While injecting, I auscultated along the course of the colon back to the cæcum, but was not sufficiently conversant with this test to distinguish the gurgling from the ordinary intestinal sounds produced by increased peristalsis. The history and examination seemed to warrant the following conclusions:—1. That obstruction set in suddenly during straining, and had existed for six days. 2. That it was complete as regards the intestinal contents. 3. That it was situated in the small intestine. 4. That hitherto there was no symptom of peritonitis or arrested circulation. 5. That medical treatment was unable to afford relief. The diagnosis appeared to lie between intussusception, strangulation by a band, and volvulus. Against the former there was the patient's age, the absence of tumour, and tenesmus, and I regarded the symptoms as decidedly too subacute for twisted intestine. It was necessary also not to overlook the possibility of sudden culmination of symptoms in a case of chronic disease, such as contraction of the intestine by bands, adhesions, or chronic stricture. Her age and the previous history of difficult defecations gave probability to this view, but it again appeared negatived by the fact that within twenty-four hours of seizure she was in excellent health and passed a normal motion. An operation was recommended, and, consent having been given in the afternoon, was performed on the 24th of September. In this I was assisted by Dr. Jackson, who administered ether, and by Mr. A. F. Hawkins. The abdomen was opened by median incision sufficiently to admit three fingers, but as the cause of obstruction could not be felt, the wound was enlarged sufficiently to admit the hand. At first no progress could be made amongst the dilated intestinal coils, which welled up and obstructed every movement of the hand; but by continuing the search towards the left colon I was able to identify that part of the large intestine by its attached mesocolon. The intestines were not allowed to prolapse through the wound, and no attempt was made to follow the continuity of their distended coils, such being evidently too difficult, tedious, and dangerous to be of practical value. Finding the colon empty, I carried the hand gently downwards and across the pelvis, exploring more fully the seat of pain below the umbilicus, and here I was soon arrested by something which there was no difficulty in making out to be a strong cord-like band buried in a loop of small intestine. By manipulation and gently pressing back the surrounding intestines, it was brought to the surface and fairly exposed to view. It was then seen to be situated at the back of the abdominal wall, to the left of the sacral promontory. The band appeared to be one of the appendices epiploicæ from the sigmoid mesocolon, which instead of floating free in the abdominal cavity had become attached by its loose extremity to the peritoneum near the sacral promontory, thus forming an arch or ring about an inch and a quarter in diameter, the plane of which was horizontal in direction. Into this trap there had slipped from above a loop of the ileum, the whole length of which would be from eight to ten inches. This portion of intestine was pale, flaccid, and empty, whilst on the other side of the ring the coil towards the duodenum was greatly dilated and of deep red color. At the point of constriction the intestine was grooved by the band, but was not ulcerated or inflamed. There was no peritonitis, the abdomen containing a little pale serum only. I am not able to verify the exact nature of the band, but it was a hollow tube, and in all probability a diverticulum from the neighboring intestine, seemingly the sigmoid flexure whence its larger end appeared to spring. The smaller end was lost in the mesentery or peritoneum at the back

of the abdominal wall. The average thickness was a quarter of an inch, and its condition was noteworthy. It was frayed and ulcerated on the surface from its own tension and the compression to which it had been subjected. It was divided between a double ligature, and the collapsed intestine filling up soon righted itself. No further exploration or replacement was made, the abdomen being closed by sutures after the little necessary cleaning.

Sept. 25th.—Has been perfectly relieved by operation; all sickness and pain gone; pulse 104; expression good.—26th: Improvement maintained; abdomen much reduced in size; pulse 96; flatus freely passed.—27th: Up to to-day every point has been satisfactory, but there has been no action of the bowels. She complains of a little pain at the right side of the wound, which has healed. As the discomfort might be due to fecal accumulation and flatus, a large enema was given, which brought back some liquid fecal matter, but gave little relief.—28th: She complains of fixed pain to the right of the umbilicus, and there swelling which had disappeared, has returned slightly; pulse 104; no sickness; restless and anxious-looking.—29th: Pain and swelling increasing. A copious enema brought away a large quantity of liquid fecal matter, which also continued to escape from her during the day, and though the abdomen generally was relieved, there was no relief to the part in question; pulse 110, with increasing anxiety and depression.

Oct. 1st.—Symptoms more severe, indicating approaching collapse. Fæcal matter and flatus continued to escape from the rectum, but without relief to local pain. She died on the following day, the ninth from the operation.

Unfortunately it was only possible to make an examination of the wound. On removing the stitches it was found that a coil of small intestine to the right was much inflated and of deep red color, and it was further seen to be in this condition from the twisting of a loop of the ileum on its own axis. At the angle of bending the intestine was in a state of local gangrenous enteritis. There was no mark of groove or furrowing by the band, and all that could be seen of this was some shrivelled discolored tissue. Peritonitis was not general, but was intense at the angle of torsion. It is difficult to understand the mechanism of this twisting. It did not exist at the time of operation, and symptoms did not appear for a day or two afterwards. Presumably it occurred during spontaneous movements of the loop which was liberated, but I do not think this portion of intestine identical with that which afterwards became twisted. I think this latter was much more probably the part next to the band, on the duodenal side. There was more congestion and distension here than elsewhere. As the rectification after division of the band appeared complete and satisfactory, I did not consider it necessary or prudent to subject the intestines to more extended examination. I cannot call to mind any point I should wish to retrace, but I certainly do regret not having reopened the abdomen.

Referring to the subject of diagnosis, it is striking to notice how far the symptoms coincide with such as we should expect to exist under the conditions revealed at operation. The sudden seizure whilst in good health, and during straining, coincides with the moment when the intestine became entangled, and the localized pain indicated the region; the previous attacks of constipation and illness were probably due to occasional entanglements in a similar way, though in all these previous ones spontaneous replacement took place. The state of the intestine, rather pale

and empty, with the general subacute character of symptoms, is explained by the size and thickness of the band, which was not tense enough to arrest the circulation of the gut. But before operation diagnosis was little more than speculation. The only point which did appear to be well established was the fact of the obstruction being in the small intestine, but even this was problematical. On one occasion I encountered a stricture of the large intestine in a patient in whom the symptoms appeared to point equally strongly in the same direction.

Granted, however, the condition diagnosed, the necessity for early operation appears almost as great and urgent as in ordinary external strangulated hernia. But there is one preliminary measure I should wish to adopt under similar circumstances—it is that of inversion of the patient. It appears just possible that in this position the loop might have withdrawn either by gravitation or peristaltic movements. The condition of the band, frayed and ulcerated, also gave indication of a possible method of spontaneous relief—viz., the giving way of these structures by their own tension and the pressure to which they are subjected. Though this form of obstruction, the true internal hernia, in which the bowel is constricted by the edges of a natural or acquired orifice, is that for which laparotomy is most typically applicable, the success hitherto achieved has not been brilliant. One triumph, such as that recorded by Mr. Alder Smith,¹ ought to go far towards vindicating the operation. Other successes are recorded, and many of the fatal cases have been under circumstances which rendered operation almost hopeless.

In performing the operation of laparotomy for obstruction the surgeon will find it of the greatest value to have a method or system of proceeding. The difficulties that meet the operator are peculiar and distinct, and arise from the great tension within the abdominal cavity and gaseous distension of the intestines. As almost to the last it remains uncertain whether it is to be completed by artificial outlet, it is certainly advisable to select for the incision any part of the abdominal wall which may be indicated by well-marked or suspicious tumour. I had great inconvenience on one occasion from not doing this, but generally there will be nothing to contraindicate the median line as the best point of section. The wound should be just large enough to admit the hand, and through it a systematic attempt is to be made to explore the cavity. At first nothing can be distinguished amid the distended coils which well up and obstruct every movement of the hand. Fortunately most forms of obstruction are close by, and readily accessible. Congenital bands and diverticula are mostly situated on one side or the other of the sacral promontory, and within easy reach of the hand. It is convenient to explore this region first, carrying the hand into the pelvis, and, if nothing is found, to feel for some portion of the intestine, which is readily identified, as the descending colon or the cæcum. The large intestine can always be identified by its attached mesocolon, and its condition, whether full or empty, is a further index to the position of the obstruction. As the cæcum receives the stress of the accumulation in cases of obstruction in the large intestine, the remainder being often nearly empty, this portion is to be specially explored, and if found empty the hand passed from it over the ileo-cæcal valve on to the small intestine, where a gall-stone, if impacted, would

be readily detected, and the tumour formed by an intussuscepted intestine would certainly be felt.

The exploration in many cases will have been conducted thus far without escape of the abdominal contents. In some cases, however, room cannot possibly be made for the hand except by displacement of intestine or by an amount of pressure which it would not be prudent to subject the inflamed intestine to. Under these circumstances, or if the cause of obstruction remains unrevealed after exploration, the present method of search had better be abandoned, and an attempt made to follow the continuity of an intestinal coil. Before withdrawing the hand, however, the operator can readily explore the ordinary hernial apertures if there is the slightest suspicion of their being engaged. It is of the greatest importance to avoid prolapse of the contents, as it is often found impossible to replace the tympanitic intestines. In a case in which I experienced this the difficulty was owing to the fact that there was no cavity to put them in. The abdomen having been freely opened had ceased to be a cavity, and could not retain the intestines until this was remade by closing up the wound. Then the difficulty was overcome, and the intestines were gradually replaced. The attempt to relieve the tension by puncture is both useless and dangerous, as an opening large enough to emit gas permits leakage of the liquid contents. To follow the continuity of an intestinal coil, search is to be made for a portion that is collapsed. This will be found in the pelvis, at the lowermost part of the cavity. It is hopeless to follow the inflated intestine. The subject is dwelt upon and explained at length in an instructive case reported by Mr. Kingston Fowler, but he errs in concluding that no record has hitherto been made of it. More than one instance will be found in recent contributions to the medical journals and societies; and in March, 1883, I drew attention to it in the *Birmingham Medical Review*. If a band is discovered its division should be made between a double ligature. The intestine is to be dealt with on the same principles that guide us in ordinary hernia. If simply furrowed by the band and discolored, it is to be liberated and the abdomen closed. If clearly ulcerated and hopelessly damaged, the injured portion is to be brought out at the lower angle of the wound for an artificial opening. Supposing the operator finds the case to be one of constriction by adhesions of a chronic nature, causing angular bends and constrictions, he should be very sparing in his efforts at their separation. The intestine in these cases is easily torn; but, apart from this danger, there is a probability of failure owing to the fact that a second band may, and frequently does, exist, and escape the operator's search, or that the intestine is permanently constricted. The abdomen has frequently been reopened for this cause, and a second obstruction found. These are essentially cases for enterotomy, which was the appropriate operation from the first if a diagnosis could have been made, and by it the surgeon will probably require to complete his proceedings.

This patient's death under the circumstances was very grievous, as a case presenting conditions more favorable to recovery can hardly be looked for, and I would ask my readers to regard the untoward termination as an exceptional and accidental incident. Such it appears to me, and for the sake of the future of the operation I would rather dwell on the indications for treatment which were met by the operation and the early promise of success which this afforded.

Birmingham.

Nulla autem est alia pro certo noscendia, nisi quamplurimas et morborum et dissectionum historias, tum aliorum tum proprias collectas habere, et inter se comparare.—MORGAGNI *De Sed. et Caus. Morb.*, lib. iv. Proœmium.

ST. GEORGE'S HOSPITAL.

SUTURE OF THE MUSCULO-SPIRAL NERVE SIX MONTHS AFTER ITS COMPLETE DIVISION, WITH ENTIRE RESTORATION OF ITS FUNCTIONS ABOUT TWELVE MONTHS AFTER OPERATION.

(Under the care of Mr. PICK.)

IN THE LANCET a few months since Mr. Holmes narrated the history of a case of suture of the musculo-spiral nerve five months after its complete division. In the remarks which follow, Mr. Holmes alluded to a patient under the care of Mr. Pick on whom an operation very similar to the one reported had been performed. The operation was thought to have failed, and the boy was discharged, having apparently derived little, if any, benefit from the treatment. Through the kindness of Mr. Coltart, of Epsom, under whose care the patient was in the first instance, an opportunity has recently occurred of examining the case, and it is found that complete recovery, with perfect restoration of the functions of the nerve, has taken place. An account of the case will therefore be of interest, especially as it resembles Mr. Holmes's case in the fact that a long period of time elapsed before any decided improvement took place.

William C—, aged thirteen, was admitted into the hospital on Sept. 21st, 1881. The history he gave was that six months prior to admission he received a stab from a pointed, half worn out table knife in the left arm, some little distance above the elbow-joint. The wound was dressed at home, and healed in about a fortnight's time. The boy was not seen by any medical man. According to his own account and also that of his mother, he was able to use his hand and arm as well as ever after the accident. Of this both the boy and his mother are quite positive. Shortly afterwards he began to notice slight dropping of the left wrist. At first he was able to extend the fingers, but in time all power of extension was lost and the wrist permanently flexed. Gradually the forearm became wasted and cold, and the loss of power more complete.

On admission there was found to be a cicatrix about four inches above and a little behind the external condyle of the left humerus. It was about three-quarters of an inch in length, and was not adherent to the bone or deeper parts. The humerus beneath seemed to be a little irregular and bossy, and pressure on the spot was attended with pain. The muscles of the forearm were wasted, especially the supinators and extensors. The wrist was dropped, the fingers flexed, and there was no power of extension. There was a sensible diminution of temperature over the forearm as compared with the other side. In the clefts of the fingers supplied by the radial nerve the temperature, as indicated by an ordinary clinical thermometer, was two degrees lower than in a corresponding position on the right side.

On Oct. 6th, 1881, an Esmarch's bandage was applied, and an incision about two inches long

was made just below the cicatrix and in the course of the musculo-spiral nerve. The nerve was readily exposed. It was found to be completely divided, the ends being separated for about half an inch, and merely connected together by a little cellular tissue. The upper end was bulbous and enlarged, the lower end wasted and bound down to the subjacent bone. The latter was freed by dissection. Both ends of the nerve were refreshed (the bulbous neuroma being removed), and were sewn together with fine catgut suture. The wound was dressed antiseptically.

After the operation the boy complained of severe pain for about six hours. This, however, suddenly ceased in the evening of the day of operation, and he passed a good night. The wound was some time in healing—in fact, it was not completely healed for about a month. At the end of a fortnight there seemed to be some power of extension returning, but it was very slight. The boy stated that sensation was much greater than before the operation; but it was believed that he rather exaggerated his feelings in this respect, in dread least another operation should have to be performed. There was no doubt, however, that the temperature of the limb gradually increased, for on his discharge from the hospital no difference could be detected upon comparing the two sides of the body.

The patient was kept under observation till Dec. 23rd, when he was discharged with instructions to show himself at the end of three months. At this time the wrist was still dropped, but he could move his fingers slightly, and it was thought by some that the extensors were a little more developed than upon his admission. The supinator longus had not improved in the least, but had dwindled down to a mere cord, which could be pinched up with the finger and thumb.

Nothing more was seen or heard of the boy until July of the present year, when he was sought out and sent up from Epsom by Mr. Coltart for inspection. The functions of the nerve are now completely restored. Sensation is perfect, and all the movements of extension of the wrist and fingers are performed as well on the one side as the other. The muscles on the injured side are not quite so fully developed as on the sound side, but then it must be remembered that the injury was in the left arm, and that he uses the right one principally in his daily work. He seems to be unable to give any accurate idea as to when the improvement first became obvious to him, but from his account it would appear to be probable that there was no very marked change for at least twelve months after the operation. The bulbous end of the nerve, which was removed at the operation, was subjected to microscopic examination, and it was found that the enlargement was principally due to increase in the perineurium, but also partly to connective tissue growing up between the nerve bundles. The growth had caused the tubules to be pressed together, the axis cylinder having been completely atrophied.

ROYAL UNITED HOSPITAL, BATH.

FIVE CASES OF TYPHOID FEVER TREATED BY COLD BATHS, FOLLOWED BY SALICYLATE OF SODA; REMARKS.

(Under the care of Dr. H. F. A. GOODRIDGE.)

FOR the following notes and remarks we are indebted to Mr. M. W. H. Russell, resident medical officer.

CASE 1.—Henry D—, aged ten years, was admitted into George ward on January 26th, 1883.

He felt quite well until four days before admission, when his appetite failed and he had headache and general lassitude. The following day the bowels became loose and he developed a cough. He rapidly got worse, cough and diarrhoea persisting.

On admission the temperature was 103° F., the pulse 124, small and feeble, and respiration 32. Patient fairly nourished. Has flushed face, cough, weakness, complete loss of appetite and diarrhoea. Stools very loose and pale. Is very drowsy and stupid. Tongue, clean tip and edges, dorsum furred. Heart irregular, sounds feeble; no bruit. All over lungs abundant sonoro-sibilant rhonchus. No expectoration. Abdomen: convex, tympanitic; abundant gurgling with tenderness in right iliac fossa. Three rose papules on the belly and one on the back. Splenic area of dullness increased, lower edge of organ not felt. Evening temperature 102.6°. Urine, sp. gr. 1020, acid, free from albumen.

January 27th.—Cough has been very troublesome. The patient has been in a torpid condition during the night, and has voided urine into the bed. There are no fresh spots. Wandered towards morning; 4 p.m., temperature 104.2°; patient placed in bath and left in for fifteen minutes; temperature of water 68° F. The effect of the bath on the pulse was marked. During the first five minutes the beats were so small as to be almost imperceptible, but during the latter ten minutes of the bath they were noticed to gain considerably in tone and volume, so that on removal from the water the pulse was decidedly stronger than before the patient was put into it. An hour afterwards the temperature was 101° F.—28th: Patient had two baths yesterday and has had two more to-day. He has to a great extent shaken off his stupor and has had no more wandering since the second bath.—31st: Several more spots have appeared. Bowels open twice daily; stools light and loose. Has daily two or three baths. The average fall of the temperature after each bath is 2° F.

Feb. 3rd.—Still requires bathing. Tympanites diminishing; cough improving; less apathy; tongue moist; pulse 96, small.—9th: Stool partly formed to-day. Bears baths very well. Cough almost ceased. Rhonchus disappearing.—12th: To-day, the twenty-first day of illness, the temperature for the first time dropped to normal. Evening temperature 101.4°.—13th: Temperature remains between 98° and 100°; ordered ten grains of salicylate of soda thrice daily. The temperature never rose again after this, and the lad made a slow but uninterrupted recovery. The salicylate was continued until March 2nd, when it was given up. He had altogether twenty-eight baths.

CASE 2.—Charles S—, aged thirteen, admitted into George ward on Jan. 26th, 1883, was quite well until six days ago, when he got headache and lost his appetite. Next day he felt too ill to work. On the third day of the illness diarrhoea came on, and has continued since.

On admission the temperature was 102.6°; pulse 116, soft. A well-grown, muscular boy, with headache, lassitude, loss of appetite, cough, pain in the belly, and diarrhoea. The tongue was coated with dirty brown fur, the tip and edges being red and dry. Over the chest scanty snoring rhonchus, with fine crackling over the bases. Blowing systolic pulmonary murmur and sharp second sound. Abdomen slightly distended; tenderness and gurgling in right iliac fossa; skin dry and hot; tache marked; spleen not felt. Half a dozen typhoid spots over the abdomen and back.

Jan. 28th.—Spots still appearing; splenic dullness enlarged; has required bathing three times.—30th: Slight nose-bleeding this morning. Spots

coming out in profusion. The temperature has not risen above 102° since the 28th.—31st: To-day (the eleventh day of the disease) the temperature dropped at 8 a.m. to 99° F. Bowels open once this afternoon; stool loose and clay-colored; contained a round worm. Ordered three grains of santolin.

Feb. 2nd.—The temperature at 8 a.m. was 98.4° F. Bowels open; no more worms. Ordered ten grains of salicylate of soda three times a day. The temperature never again rose above 100° F., and the patient convalesced rapidly. Continued taking salicylate until Feb. 24th.

CASE 3.—Thomas F—, aged twelve, admitted Jan. 26th, 1883, into George ward. Was quite well on the 23rd, and took his meals heartily. Next morning felt ill, vomited, and lost appetite. Yesterday the bowels were very loose, and patient developed a slight cough.

On admission the temperature was 102.6°, pulse 124, respiration 24. Complaints of cough, thirst, headache, loss of appetite, and diarrhoea. Sonoro-sibilant rhonchi all over the lungs. Distension of abdomen, no gurgling; tache marked; no spots; area of splenic dullness not enlarged.

Jan. 28th.—Two spots found this morning on the abdomen. Tongue dry and furred; tenderness and gurgling all over the abdomen; bowels open freely; loose clay-colored stools. Spots continued coming out until Feb. 6th. Patient had altogether eighteen baths. On Feb. 12th, the twentieth day of illness, the temperature fell to 97° F., and he was ordered ten grains of salicylate of soda thrice daily, for three weeks. He recovered well and quickly.

CASE 4.—George M—, aged fourteen, admitted into George ward on Feb. 6th, 1883. Came in on the sixth day of illness. Temperature 102.4°, pulse 104, respiration 36. Distension of abdomen, with tenderness and gurgling; spleen felt projecting an inch and a half below the ribs. No spots all over chest; sonoro-sibilant rhonchi.

Feb. 7th.—About a dozen rose-colored spots have appeared. Had four baths to-day; after each bath the temperature falls to about 101° F., where it remains for about two hours, after which it rapidly rises again to 104°.—8th: Fever still high; five baths to-day. Abundant whistling râles over the chest. Pulse 116. Ordered two ounces of brandy daily.—10th: Five baths yesterday and four to-day. A little faint and blue after the last three baths; given a teaspoonful of brandy after each; typhoid stools.—12th: Gums are bleeding and are decidedly spongy.—14th: Gums still oozing.—23rd: Has had altogether thirty-four baths. To-day the temperature has dropped for the first time to normal. Ordered ten grains of salicylate three times daily for fourteen days. Made a good recovery.

CASE 5.—James P—, aged twelve, was admitted into George ward on February 6th, 1883. He came in on the third day of illness. A weakly, strumous-looking boy. Tongue coated with a creamy white fur, clean tip and edges; face flushed. Abdomen slightly distended; tache marked. Slight tenderness and some gurgling in the right iliac fossa. One rose spot in the right flank. The lower edge of the spleen can just be felt below the ribs. Breath sounds clear. Temperature 101.8°; pulse 112.

February 7th.—Quite a crop of spots have appeared during the night. Bathed three times.—10th: Spots continue to appear. The one noticed on admission is fading. The patient has had ten baths so far.—12th: Tongue clammy; lips and teeth covered with sordes. Given a weak solution of permanganate of potash to rinse his mouth. Bowels open about once a day, loose stools. Two baths yesterday and one to-day.—15th: One bath

yesterday.—18th: A tender reddened swelling over the right angle of the jaw.—22nd: Since the 18th the temperature has kept steadily between 101° and 102° F. The gums are to-day spongy and bleeding. The temperature has dropped to 97.2°.—23rd: The bleeding from the gums continues, and in addition this morning the patient is losing blood from the nose and left ear. The urine passed is as dark as porter and contains a large percentage of blood; bowels not open. Ordered a mixture containing ten grains of tannic acid and twenty minims of liquid extract of ergot, to be taken every four hours, with ice to suck. The temperature has risen again to 101°. 8 P.M.: Bleeding continues from gums and a little from the nose, it appears to be a general oozing. The gums are spongy and fungating. Bowels open once this afternoon; stool contained about half a pint of blood. There are no purpuric spots or patches about the body.—24th, 8 A.M.: Temperature 102°; sponged; the urine still contains a large amount of blood; oozing from the gums abating; bowels open twice during the night, each time stools contained blood. Ordered two grains of acetate of lead, ten minims of dilute acetic acid, water to half an ounce, every four hours. Two lemons daily.—25th: Still oozing from gums; bowels open three times, stools largely made up of blood; urine like porter. The temperature was maintained at 101°.—26th: Gums almost ceased bleeding; bowels open three times, blood diminishing; urine still highly charged with blood. The temperature was 99.6° at 8 A.M.; pulse very small and weak; hardly perceptible. Patient blanched.—27th: Bowels open twice, small quantity of blood each time; very slight oozing still from the mouth; less blood in urine. The temperature 98.6°.—28th: All bleeding ceased; patient takes nourishment and stimulant well. Repeat mixture three times a day. The temperature remains normal.

March 3rd.—Has rallied well during the past three days; fed every fifteen minutes. Omit mixture.—6th: No further loss of blood. The lump over angle of jaw noticed before has remained in abeyance until to-day; it is now painful and fluctuates distinctly; bowels open once, stool loose, no blood.—7th: Abscess over jaw lanced and about two drachms of pus evacuated. Ordered five grains of citrate of iron and quinine three times a day. Patient has progressed uninterruptedly since, and is now quite convalescent.

Remarks.—The foregoing cases present several features of interest, both clinical and therapeutic. The patients were all boys under fifteen years of age, were attacked much about the same time, and were all inmates of a neighboring industrial school, where, being under constant supervision, the onset of the disease was ascertained with tolerable accuracy. Cases 3 and 5 were admitted on the third day, Case 1 on the fifth, Case 4 on the sixth, and Case 2 on the seventh. The spots were plentiful, and appear in each case on or before the seventh day. In Case 3 they appeared on the fifth day, in Case 1 were present before the fifth day, and in Case 5 there was an indubitable typhoid spot visible on admission, the third day of illness. This latter is an exceptionally early appearance even for a child. In three of the cases there was bronchial catarrh of considerable severity. Case 2 was a mild one; its chief point of interest was the presence of the round worm, a by no means unreal element of danger, as evidenced by a former case of Dr. Goodridge's, where perforation appeared to be directly due to the presence of such a parasite. The most important clinical point was undoubtedly the occurrence of scorbutic symptoms in two of the cases. Mild in Case 4,

they were in Case 5 sufficiently severe to seriously threaten his life. This is a complication which, so far as I can discover, is of considerable rarity in the annals of typhoids. In both cases it appeared at a fairly advanced period of the fever disease—in Case 4 on the twelfth day after the fever, which had been very severe, had spent its force, and in Case 5 as late as the nineteenth day of the disease. In this latter case, the hemorrhage being severe, its onset like an ordinary typhoid hemorrhage was signalized by a sudden drop in the temperature. This, however, quickly rose again, whilst the hemorrhage was still going on, and transcended its former height. Suspicion was directed to the dietary of the school: but this on investigation was found to contain an abundance of antiscorbutic elements. To advert to some points in the treatment. The diet in all these cases was restricted to iced milk. They were treated strictly antipyretically, and the only antipyretic used was cold water; no drugs. The temperatures were taken every four hours; and whenever 103° F. or higher was registered, the cold bath was called into requisition. Sponging with ice-cold water for ten minutes was employed whenever the temperature stood between 102° and 103°. An hour after each bath the thermometer was used, with an average result of showing a drop of two degrees in temperature. The efficacy of the baths in keeping the temperature down is amply shown by the charts, more especially in those cases which had the advantage of early treatment. In Case 4, where the pyrexia had obtained a good start, their effect was less well shown at first, though after having once broken the neck of the fever (in this case on the fourth day of treatment), they succeeded in making it fairly tractable. Some of the other good effects noticed after baths were (1) the almost invariable bracing-up of the pulse after the first rude shock was over; and (2) the banishment of delirium. The baths were well borne in Cases 1, 3, and 4, not appearing to exercise any baneful influence on the severe bronchial symptoms. As soon as the temperature had once spontaneously dropped to normal, the patients (with the exception of Case 5, who was deemed too prostrate) were placed upon salicylate of soda, after the plan of Prof. Immermann, as advocated by Dr. Cayley, in his Croonian Lectures on Typhoid, and practiced by him in his wards. This was done with the original view of guarding against relapse, to which accident, it is shown, the cold bath treatment rather predisposes. In two cases it slowed the pulse to 60; but no other depressant or toxic symptoms of the drug were noticed. The patients took it well, and thrived whilst taking it. The exhibition of this drug during early typhoid convalescence appears to be a valuable addition to the bathing treatment, influencing in a distinctly favorable manner the number of relapses. One valuable property the salicylate possesses is to check the ravenous cravings for food in early typhoid convalescence, and thus diminish the risk of indiscretion in diet. A point worthy of note in Case 5 was the happy way in which the acetate of lead checked the hemorrhage after the ineffectual administration of other drugs.

ST. THOMAS'S HOSPITAL.

UNUNITED FRACTURE OF PATELLA; OPERATION; CURE.

(Under the care of Mr. SYDNEY JONES.)

For the notes of this case we are indebted to Mr. W. H. Battle, surgical registrar.

J. P—, aged twenty-eight, a laborer, was admitted on Sept. 7th, 1882, and left the hospital, cured, on Feb. 2nd, 1883 (149 days). Seven months

previous to admission he fell down and fractured his left patella. The knee was put up with strapping and kept on a hard splint for eight weeks, during six of which he remained in bed. He resumed work as a laborer about the ninth week. The knee was fairly strong until four months before admission, when a piece of iron fell across the same knee. This, it would appear, produced acute inflammation of the joint, and from that time he was unable to walk. His general health was good.

On admission it was found that the left patella had been fractured transversely, the fragments being separated by an interval of two inches; there appeared to be very little fibrous tissue between them, and they could be approximated fairly easily. The fracture had crossed the bone about the middle, and the outline of the condyles could be plainly distinguished. There was no fluid in the joint. The leg was fairly muscular, but not large; the patient could not, however, walk more than a few steps. His general health was good. The urine contained no albumen.

Oct. 11th.—The exact distance between the margins of the fragments was two inches and a half. Mr. Sydney Jones decided to bring the fragments into apposition by operation. This he did in the following manner:—Ether having been administered, an incision about six inches in length was made along the front of the joint, in the middle line, and in the long axis of the limb; the skin was reflected to each side and the fragments exposed. These were found connected by means of thick fibrous tissue. This was separated from the fragments, and a thin transverse section taken from each fragment. The synovial membrane of the joint was thickened, but the joint itself was otherwise healthy. An attempt was now made to approximate the fragments, but they could not be brought into close contact. The expansion of the fascia of the thigh to the quadriceps extensor muscle and sides of the upper fragment was then divided on each side to the extent of about an inch upwards; but this did not prove sufficient; accordingly the rectus muscle was subcutaneously divided about three inches above the patella. The fragments did not come well together until the posterior edge of each had been removed. Two holes were drilled in each fragment from the anterior surface to the middle of the cut surface of the fragment, and two sutures of thick copper wire covered with silver were inserted, and the two portions of the patella completely brought together. Three turns were taken in each suture from within outwards; lateral incisions were made, and drainage tubes placed in each. The wound was closed with silk sutures and antiseptic dressing applied. The spray was used throughout the operation. The limb was placed on a straight excision splint, strips of flannel soaked in plaster of Paris being applied along the front and the whole carefully bandaged. Three hours after the operation there was found to be slight hæmorrhage; the wound was redressed, and the limb elevated. Evening temperature 99° 6". Patient was very restless during the night, and had two hypodermic injections of morphia. Next morning he was in a good deal of pain, and had vomited several times. Morning temperature 100° 2", evening 102° 4"—13th: Another restless night. The wound was dressed in the afternoon, and a collection of blood-stained fluid was found above the upper border of the patella. The top stitch was removed and a fresh tube placed across the joint under the patella, being brought out through the lateral opening; the smaller pieces were not replaced. Morning temperature 101° 2", evening 102° 2".—20th: The wound was redressed on the 15th and again today, when all the remaining sutures were re-

moved. The wound was firmly united, excepting in the upper part, where there was a small collection of pus; the puncture made for tenotomy had to be opened up for a similar reason. The morning temperature on the 15th was 102°; 17th, 100° 4"; 19th, 98° 4"; 20th, 99° 4". Evening temperature: 15th, 102° 2"; 17th, 101° 8"; 19th, 100° 2"; 20th, 100° 8".—24th: As the wound when dressed appeared to be irritated by the carbolic acid dressings, eucalyptus was substituted. The collection above the upper fragment is quite gone. The temperature has been lower until this evening, when it is 102° 4".—27th: Wound redressed.—31st: Wound redressed. There was some puffiness to inner side of the patella.

Nov. 11th.—Wound redressed on the 4th, the 8th, and again to-day; the upper part is now healed. Short drainage-tubes placed on each side. General health good. Since the 24th the temperature in the morning has risen from 98° to 100° 2"; in the evening 99° 8" to 101° 8".—24th: Wound redressed; the leg was removed from the excision splint and placed on a MacIntyre; the wire sutures were removed; there was close union between the fragments of the patella. Forty-four days after operation the drainage-tube on the outer side of joint was removed.—29th: Wound redressed, and all the drainage-tubes removed; there was a good deal of discharge in the dressings. Before the 26th the evening temperature was nearly always between one and two degrees higher than in the morning; since then (with one exception, 25th, 100°) it has not exceeded 99°.

Dec. 22nd.—Antiseptics discontinued. There are still two discharging sinuses on the inner side of the patella. The leg was put up in a posterior plaster splint, the foot being left free. The temperature has been normal since the 3rd (13th, P.M., 100°). The patient's general condition is good.

Jan. 4th.—Slight rise of temperature, due to the formation of an abscess on inner side of the patella; this was opened on the 5th, and a considerable quantity of pus evacuated. The other sinuses had quite healed.

When the patient was first allowed to get up there was cedema of the leg and feet, but as he got stronger this disappeared, and he was able to do without a bandage, which he at first used. When he left the hospital he was able to walk a short distance without the aid of a stick, and the joint was capable of considerable flexion. The union between the fragments was quite firm, and the patient was much pleased with the increased usefulness of the leg, and as he was inclined to persevere in his efforts to get increased flexion of the joint, there was every prospect of his having an almost perfect limb.

GUYS HOSPITAL.

DISTENSION OF FRONTAL SINUS; INCISION; DRAINAGE; CURE.

(Under the care of Mr. BRYANT.)

For the notes of the following case we are indebted to Mr. Linnell.

Eleanor P—, aged twenty three, was admitted on Jan. 13th, 1882, into Lydia ward. She had always been weak, and always irregular in her menses. In childhood she had measles and small-pox. She had been in the hospital under the care of Mr. Forster for diseased bone in the foot six years ago. Mr. Forster excised the ankle, and afterwards amputated the leg. The stump never really healed, and about three or four years ago she knocked the stump and the skin gave way, so that the bone became exposed and remained so.

On admission, the patient looked fairly healthy. The stump was conical, and fairly riddled with shallow sinuses, and was scattered over with patches of dried serum. There was considerable pain. At the inner corner of the right eye was a bilobed swelling, first noticed five years and a quarter ago. The swelling was painful, and the pain increased when hot fomentations were applied. After its first appearance it had more than once disappeared, and had not generally given any pain until a fortnight ago, when the external lobe showed itself for the first time. The skin over the second lobe was of a reddish yellow color, tender, and very sensitive. The lobe did not diminish on pressure, nor did it apparently infiltrate the skin. There was fluctuation between the two lobes. There was no epiphora.

On Jan. 27th an oblique incision was made over the orbital tumour, when a semi-purulent sanious discharge escaped. A ridge of bone was felt leading into a cavity, which proved to be the frontal cell. A spiculum of bone was removed with the bone forceps and a chisel, and a drainage-tube was passed from the cavity down the lacrymal duct into the nasal cavity and through the nostril. The angular artery was twisted. The cavity was next syringed out with iodine water, when a thick clotted purulent discharge escaped. This fluid was rather glutinous; it contained some columnar ciliated cells looking quite fresh, but the contents were chiefly degenerating pus cells and débris, and many large granular mucous corpuscles. The edges of the wound were stitched together with carbolized catgut.

Feb. 15th.—Wound healed. There is still fulness internal to the line of incision, and upon squeezing something was felt to flow into the nose. There was no epiphora. The movements of the eyeball were good.

On Feb. 27th she was discharged convalescent.

On June 1st, 1882, she reappeared in the ward, when the orbit was natural, the sinus having closed.

This case had very much the appearance of an orbital exostosis, and its true relation was not recognized until a free incision had been made down to the bone. In the last vol. (xxv.) of the Guy's Hospital Reports Mr. Higgins has published some cases of the same kind.

MONTGOMERYSHIRE INFIRMARY.

CASE OF PAROTITIS FOLLOWED BY ORCHITIS AND MENINGITIS; HIGH TEMPERATURE; RECOVERY.

(Under the care of Mr. MONRO.)

For the following notes we are indebted to Mr. G. H. Healy, house-surgeon.

W. B—, a lad of fifteen years, of considerable aptitude for mathematics and other brain work, and of nervous temperament, was admitted on August 2nd, 1882. Previous to admission he had had an attack of mumps, from which he had apparently recovered, but upon returning from a short walk he felt much depressed and feverish, had a rigor and was obliged to take to his bed. The temperature next morning was 101.2°, with slight frontal headache, brown tongue, hot dry skin, and hard rapid pulse, but no vomiting. Temperature in the afternoon 105°, rising in the evening to 106°, with low muttering delirium and tenderness of scrotum. A saline mixture and a purgative were given.

On Aug. 4th the temperature remained the same. There was impaired resonance of the base of the right lung. The scrotum was much swollen,

and very painful, the delirium continuing and increasing towards night. Aconite in small doses was added to the mixture, and cold was applied to the head. The scrotum was poulticed and supported.—5th: Temperature, morning 106°, evening 107.2°. Pupils much dilated and insensible to light; increased delirium; patient very restless, rolling his head from side to side; bowels costive. Wet sheet packing was applied, which had the effect of lowering the temperature to 105°; and a purgative enema was given, which did not act. The orchitis appeared to be subsiding.—6th: Temperature, morning 105.4°, evening 106°. The patient had violent delirium towards evening with muscular twitchings on the left side. His head was shaved and blistered, and, as the bowels had not acted, he was given croton oil, and at night a dose of bromide of potassium, and had ice applied to the head.—7th: Temperature, morning 105°, evening 105.4°. Delirium was very wild and maniacal. He was given bromide of potassium every three hours with henbane. The bowels not having acted, an enema was given, and the patient passed some very hard, dark, and offensive stools. Six leeches were applied to the temples.—8th: Temperature, morning 105°, evening 105.4°; the pulse thready and fluttering and tache cérébrale well marked. The patient was in an extremely prostrate condition, had apparent difficulty of deglutition, and would not try to take his medicine, getting very excited at the sight of it. Subsequently coma set in. Nutrient enemata were given of essence of beef, eggs, and brandy in small quantities. Sinapisms were applied to the back of the neck, the cardiac regions, and the calves of the legs. He was very restless during the night, but improved somewhat towards morning, but slept very little.—9th: The temperature fell to 103°, but the delirium became extreme, patient requiring several people to keep him in bed. He was able, however, at times to recognize faces, and expressed great aversion to some; made violent efforts to bite the hands of those holding him, and was most impatient of the restraint placed upon him, begging to be let loose and asking the attendants to put their fingers in his mouth that he might, as he said, show that he did not intend mischief. He could not swallow, and shouted at the top of his voice when asked to try to doze. The pulse was hardly perceptible after these paroxysms and prostration very great. Nutrient enemata were with difficulty continued. The head was again blistered and ice subsequently applied. The orchitis had disappeared.—10th: Temperature morning and evening, 102°. The patient having passed a wretched night was calmer in the morning, and took nourishment in small quantities when pressed. Essence of beef and iced champagne were given by the mouth. The pulse became stronger subsequently. The bowels being obstinate, olive-oil enemata were given, which acted but caused considerable pain, the fæces being very hard and requiring mechanical removal.—11th: The patient had passed a better night with but little delirium. He was quite sensible, and took nourishment well, and generally had much improved. Pulse better, and temperature nearly normal.

From this time the patient continued to improve daily, the head symptoms disappearing gradually, but he continued for some days in an extremely prostrate condition, and required great care in nursing. In a fortnight, however, he was able to get up, and although he still had a weak pulse and considerable dilatation of the pupils, he had otherwise much improved, could assimilate plenty of nourishment, and, in consequence, with tonics and iron with strychnia in small doses, he

was in a condition to be discharged shortly afterwards.

The patient has been under observation since his discharge, now more than six months ago. He suffered for a considerable time from difficulty in walking, his gait being unsteady and incoördinate; as also in speaking, making impulsive efforts to utter his sentences as quickly as possible, with incomplete enunciation of the words. He had also marked agraphia. His pupils continued to be dilated, and mentally he was subject to much excitement when spoken to. The electric current was used to the muscles of the throat, and phosphorus, valerianate of zinc, iron, quinine, extract of malt, and cod liver oil were prescribed. At the present time he is almost as well as before his illness, and gains rapidly in physique.

It may be remarked that the temperature in this case was higher than is usual in meningitis. There was also little headache and an absence of vomiting. Yet the symptoms generally pointed to metastatic meningitis which occasionally, though not much referred to in standard medical works, follows parotitis. It is also worthy of note that it did so in the case of a boy of more than ordinary mental activity and excitability, which possibly may have had something to do with its occurrence. The patient's brother had an attack of mumps at the same time without a bad symptom.

LEICESTER INFIRMARY.

NOTES ON A CASE OF HYDROPHOBIA PRESENTING SOME PECULIAR SYMPTOMS; NECROPSY; REMARKS.

(Under the care of Dr. COOPER.)

For the following notes we are indebted to Mr. C. J. Bond, F.R.C.S., house-surgeon.

A healthy agricultural laborer, aged fifty-six, was bitten by a large retriever dog, on Jan. 20th, 1883, on the left hand. The wound, or at least one of the scratches, continued in an inflamed discharging state for some time, and, in fact, was only soundly healed fourteen days before admission. The man, however, paid but little attention to it, and went about his work as usual until April 16th, when he began to get rather nervous and fidgety about his hand. On the 19th, on getting up in the morning to go to his work, he felt pain in his chest and some difficulty in breathing, and also in swallowing, and he also vomited; this nervousness and pain on swallowing increased on this and the following day, and he was admitted into the infirmary on the morning of April 21st, when his condition was noted as follows:—The patient is a strongly made, florid man. He lies quietly in bed, and answers questions quite rationally. He does not attach any importance to the bite, which shows no signs of redness or inflammation, and has apparently no suspicion of the nature of his disease, though he expresses himself as feeling very ill. Although generally quiet, the noise of falling water poured out, out of his sight, causes him to set up in bed; his face assumes an anxious, frightened look, the respirations become quick and snatchy, and he implores that no fluid may be given him. When a glass of water is put into his hand and he is asked to drink, he seems agitated, says that he is not afraid of it but cannot drink; he raises the glass a little, then shudders and pushes it away, complaining at the same time of pain at the epigastrium and base of chest. As he lies quietly in bed the respiration is from 16 to 20 per minute; pulse 110, varying somewhat in force and frequency from time to time, the occurrence of a period of excitement increasing its frequency and lessening its force, and producing irregularity in

the rhythm, and intermission occasionally occurring. He is able to open his mouth widely and keep it so when asked, the pupils are equal, and react to light, there are no spasms in the sense of any tonic contraction of any muscle or group of muscles, and the temperature at this time, 11 A.M., is 98°. Urine acid, sp. gr. 1025; no albumen. 6.30 P.M.: After several unsuccessful attempts patient has now passed over half a pint of urine, which contains a trace of albumen. The act of micturition caused no spasm or inconvenience to the patient. 7.30: Patient is now very restless and seems in a jovial mood, he tries to shake hands, kicks off the bedclothes, and as the attacks (that is, the feeling of agitation and oppression, the hurried breathing, and the quickened pulse) come on, he grasps the hand of a bystander, saying that he is thus much relieved; he very frequently spits out frothy saliva very energetically, as though afraid to retain it in his mouth. 12.30 (midnight): Patient has changed considerably, sits up in bed almost constantly, is still conscious and wishes to see his friends; his face has, however, a very anxious and, at times, a startled expression, and he is constantly spitting out a mixture of frothy, blood-stained mucus and saliva on to the floor, refusing to spit into any vessel. Respiration is now more frequent, and accompanied with bronchial and tracheal râles, and temperature has risen to 99.2° in rectum.—22nd, 11 A.M.: The mental condition of the patient is gradually more resembling that of mania. His face is flushed; the conjunctivæ suffused. He is much less sensitive at the approach of strangers, and pays no attention to the sound of falling water, though he still refuses to drink. Water, poured into his mouth, causes no spasm, and he occasionally swallows saliva; the plantar reflexes are abolished; knee-jerk present in both legs, and both testicles are much drawn up. The constant spitting of mucus and saliva continues, though the former is not now blood-stained. The respiratory sounds are clearer, and there is occasional vomiting of a green, bile-stained fluid. The temperature is now, noon, 104.4°. 3 P.M.: Patient is now unconscious; his face is very dusky; the vomiting of this green fluid is almost constant; pulse very quick and feeble, but regular. At 3.15 P.M. respiration ceased while patient was in the act of vomiting. The temperature in the rectum, forty-eight minutes after death, was 107° F., and rigor mortis was well marked two hours after death.

At the post-mortem examination it was found impossible in this case, as in previous ones, to associate each symptom with a definite pathological lesion. The blood was found coagulated, not fluid as usually described; little or no endocardial blood-staining, so common in septic diseases, and no change which could be called specific was observed by the naked eye in any organ, except that on making sections through the spinal cord and medulla; the latter and the cord as far as the lower cervical region appeared softer and redder than in the dorsal and lumbar regions. Microscopical examination of the blood at various stages of the disease (by Koch's method) showed nothing abnormal beyond division of the nuclei in the leucocytes and some round deeply stained refractive bodies aggregated together, which might or might not have any specific importance. Examination of the saliva during life, and from a fresh section of the gland immediately after death, showed nothing beyond the usual organisms associated with that secretion when obtained from the mouth. Sections of the sublingual gland stained with logwood showed marked injection of the organ, with numerous granular bodies among the epithelial cells, which resembled leucocytes. Sections of the hardened medulla and cervical cord certainly

showed an injected condition of the grey matter, with numerous granules and extravasation of leucocytes around the vessels, as described by Dr. Gowers. Further, considerable difficulty was experienced in hardening the medulla and cervical portion of the cord in Müller's fluid; not so in the lumbar region.

Remarks.—In order to correctly estimate the value of the cerebral symptoms in this, as in any case, it is necessary to remember that the patient was a strong, steady farm-laborer, a man in whom the nervous system (as in most men of that class) was previously to the disease in a condition of very stable equilibrium; and although apparently a little nervous about the bite before his illness, he ceased to attach any importance, or to allude to it, after his admission. Regarding the disease as due to some poison acting on the central nervous system, it would seem that in the order of time the respiratory centre was the first to be affected by it, then the cardiac, and, finally, perhaps the vomiting centre. Further, the irregularity and intermission of the pulse, so marked in the early stage, quite passed away before death, and, though cerebral function was much exalted at times, the mental dread of water also quite passed away. Bearing on the selective action of the poison on the medulla is the fact that there was no great radiation of stimulus, no tetanoid spasms, the most marked fit merely resembling the action of a person when getting into a cold bath, together with a superadded emotional condition as though an impression were produced on the respiratory centre like that produced by cold affusion; how far the mental state is one of association or of distinct cerebral poisoning yet remains to be proved. Another feature is that the temperature, said to be usually raised one or two degrees, though normal on admission, rose gradually to 99·4° in twelve hours, to 104·4° in twenty-four hours, and was 107° in the rectum forty-eight minutes after death.

Any detailed description of the treatment adopted has been purposely avoided, for this case, like every other, shows that we have not yet discovered any specific for hydrophobia; at the same time the patient was evidently saved a large amount of mental dread and pain from the administration of chloral and morphia in large and frequent doses, the former by rectal injection, the latter by hypodermic injection.

MANCHESTER WORKHOUSE, CRUMPSALL.

NOTES ON A CASE OF HYSTERICAL (?) HEMI-ANÆSTHESIA IN A MAN.

FOR the following interesting notes we are indebted to Mr. C. B. Voisey, M.R.C.S.

W. M.—, a strong and powerful-looking man, was admitted on March 8th, 1883, in such a weak-minded and melancholic condition that it was some days before anything like a rational history could be elicited from him. The history was as follows:—For the last sixteen years he had been a carpenter, serving with a brigade of artillery in India. Up to three years ago he had always enjoyed good health, but had been a constant and free drinker. He stated that he had never had syphilis. During the Afghan campaign he received a bullet wound on the right side of the sagittal suture, extending from the coronal suture in front to the lambdoidal suture posteriorly. The wound healed rapidly, but was complicated six weeks later by the formation of an abscess, which was opened antiseptically under chloroform, but he does not know whether any bone was removed. On being discharged from hospital he drank

heavily, and in one of his bouts of intoxication he lay down in a marsh, where, becoming insensible, he was picked up and transferred to the hospital suffering from sunstroke. He remained under treatment for three months, and ever since had been troubled with pain and lightness in the head, numbness and weakness in the right side. Whilst in India he had had dysentery, slight attacks of liver complaint and ague. He left India and returned to England in December, 1882, and was subsequently received into Netley, whence he was discharged in January last. From that time, up to a few weeks ago, he had been travelling up and down the country, spending the money he had saved, until about a month ago he was drinking in a public-house in Manchester and was there seized with some kind of fit, and thence taken in an insensible condition to the Manchester Royal Infirmary, and afterwards transferred to Workhouse Hospital.

On admission to the workhouse he was in a very low desponding state of mind, and from the very few remarks he made, it was gathered that he contemplated suicide. On March 10th the patient complained of very great and constant pain over the eyebrows, and suffered from anorexia. It was also found he was suffering from anæsthesia of the right side, which involved the face, neck, trunk, arm, and leg, but sensation was not quite lost in the sole of the foot. Taste was lost in the right half of the tongue, and there was partial deafness and complete loss of smell on the same side. The right side of the tongue, right half of the fauces and the mucous membrane of the right cheek were likewise anæsthetic. The fields of vision of both eyes were much restricted, but especially so in the right, which was also achromatopsic, the patient asserting that everything appeared white. The left eye was not so much affected as the right, but although the man was able to distinguish that blue and yellow were dissimilar colors, he was unable to recognize the individual colors properly. There was no optic neuritis, and the pupils were equal, contracted, and responded to light. The right, or affected side, was paler than the left, and did not readily bleed when pricked. The patient himself ran a large needle nearly through the whole thickness of the forearm without blood flowing. The temperature in the right axilla was 96·2° F., in the left 97·8° F. The power of distinguishing between heat and cold was lost on the anæsthetic side. The tendon reactions were normal, and there was no ankle clonus and no paralysis. Up to March 15th the patient's condition had continued unchanged so far as the nervous symptoms were concerned. He was still very despondent, and had persistently refused to take solid food. His breath was very offensive; the tongue was covered with a brown fur; and the bowels were constipated. On March 18th the patient was seized with bilateral convulsions; but the nurse is convinced he was not completely unconscious at any time during the attack. After the fit had passed off it was found that hemiplegia had developed in the right, or anæsthetic side; but the face and tongue were not implicated in the paralysis. Motor power reappeared in the arm and leg at the end of two days, the patient remaining thereafter in much the same condition as he was before the fit. On the 21st, aphonia had become developed, and the voice was reduced to the faintest whisper, although articulation was still perfectly distinct. On March 23rd, the faradaic current was applied to the affected side and over the larynx, as aphonia was still present. The patient objected to this treatment, and after struggling in vain to prevent the application, he shouted lustily, having suddenly found the use of his voice; but on discontinuing the cur-

rent the aphonia returned. The same evening, after being told that the electricity was to be applied in the morning, he attempted suicide by strangulation, but was prevented by the timely interference of the nurse. The current was applied on the 24th, but on the 25th the patient suddenly recovered his voice before the application was renewed. On the 27th tactile and thermic sensation returned in the whole of the right side, except the face and upper part of the neck, but analgesia persisted, and the special senses were still affected. He afterwards complained that the left extremities were heavy and numb, and on pricking the skin with a needle it appeared that the left side was less sensitive than the right. The temperature, too, was more nearly equal on the two sides, being 97.4° F. in the right, and 98° F. in the left axilla. From this last stage until April 21st his condition was very various. One day he would be more cheerful, and lose many of his special symptoms, but only to relapse again in a very short though varying period. About April 14th he appeared better, both mentally and bodily, and was permitted to get out of bed, and by way of occupation was allowed to assist the other patients in cleaning the wards. He had not been occupied in this way long before he took advantage of an opportunity to make elaborate preparations to commit suicide by hanging, but was again unsuccessful, by reason of the timely appearance of one of the attendants. The case was hereupon regarded as one requiring close and careful watching, and the patient was accordingly transferred to Prestwich Lunatic Asylum. When the patient was sent away, the hemianæsthesia and hemianalgesia had nearly disappeared, but the inability to distinguish between heat and cold remained. The two sides more nearly corresponded as regards temperature, color, and the readiness with which they could be made to bleed on pricking. Hearing was more acute, taste and smell more nearly normal. The man could distinguish colors with both eyes, though there was still slight hesitation and evident difficulty when using the right. Objects when placed within a distance of two feet appeared to both eyes as blurred and indistinct. This difficulty, which has been experienced ever since the man came under observation, may probably be due to the contracted state of the pupils.

By the kindness of Dr. H. G. Murray it has since been ascertained that the patient on admission to the Prestwich Asylum was low-spirited and suspicious, fancying that he had been drugged, and that the day after admission he commenced to assist in the cleaning of the wards; that in a few days, the depression having passed off, he was employed in the joiner's shop, where he worked well and cheerfully until June 16th, when he absconded, and has not since been heard of.

MANCHESTER ROYAL INFIRMARY.

CASE OF EPITHELIOMA OF THE SCROTUM IN A YOUTH.

(Under the care of Mr. HEATH.)

FOR the following notes we are indebted to Mr. John Sheldon Withers, M.R.C.S., late house-surgeon.

W. L—, aged eighteen, a block outter, was admitted to hospital. No tendency to malignant disease discoverable in his family. Patient had always had robust health. No history of injury or irritation. About a year before admission the patient noticed a small hard swelling as large as a marble in the right and lower part of his scrotum. It grew rapidly, reaching the size of a hen's egg in less than three months. Four months later (it

had spread far in the meantime) the right inguinal glands began to enlarge and soon afterwards the left. It did not cause him pain till nine months after its commencement, when a nightly aching began from which he has not since been free. His parents discovered it only when far advanced by noticing a peculiarity in his gait.

Condition on admission:—Pain has now made his expression careworn, but for this he might be taken as the type of a healthy country lad. He is of fair complexion, rosy cheeked, and well nourished. The growth involves the whole of the scrotum; its surface is irregular and nodulated. The nodules are of very variable size, some being no larger than a marble, whilst others are as big as a small orange. At its underpart is the mouth of a sinus, which leads to a cavity in the centre of the mass. Here, whilst growth is going on actively outside, a process of destruction is at work, evidenced by the constant discharge of a thin, yellowish, opaque fluid, and occasionally of blood in large quantities. On either side, the inguinal glands form two large tuberos masses adherent to the deep structures. In the neighborhood of the right of these, one testicle can be felt, the position of the other cannot be made out. The growth is nowhere tender to the touch, and is of uniform, moderate hardness. Owing to frequent hæmorrhages, he became rapidly worse, and died, wasted to the last degree, four months after admission. After death, the testicles were found to be quite healthy. A microscopical examination, made by several pathologists, among whom were Drs. Dreschfeld and Young, of Owens College, proved the tumour to be an epithelioma. A necropsy was not allowed.

GENERAL DISPENSARY, NOTTINGHAM.

ANEURISM OF THE INTRA-PERICARDIAL PORTION OF THE AORTA; SUDDEN DEATH FROM RUPTURE; NECROPSY.

FOR the following interesting notes we are indebted to Dr. M. Collins.

On the morning of May 5th, Mrs. B— was suddenly seized with præcordial distress whilst talking to some of her friends. She expired in a few minutes and before the arrival of the medical attendant, though her house was not two hundred yards distant from the hospital. The history of any previous illness was very indefinite. A week before her decease she quarreled with her husband, and had charged him before the magistrates with assault. Sudden death under such circumstances assumed an interesting nature, pathologically as well as medico-legally.

Necropsy, forty-eight hours after death—Apparent age fifty-five; body well nourished; no marks of violence. When the thorax was opened the pericardium was found distended with blood. Further examination revealed a very small sacculated aneurism immediately above the right coronary valve. This had ruptured into the pericardium. The opening was small, only sufficient to admit a medium-sized probe. There was no regurgitation through the valves. The aorta was atheromatous, as evidenced by "patchy thickenings and unevenness on the inner surface."

Dr. Hayden has pointed out that aortic aneurisms never attain a large size when they are exposed to the maximum of reflux from the aorta. The symptoms and acoustic signs are very indefinite during life. Death was very sudden, and without any warning, as it usually is in such cases.

A coroner's inquest was held, and the question naturally asked was, Did ill-treatment tend to accelerate her death? There was no evidence that it

did. She had not lived with her husband the previous week. The grief and anxiety consequent on her domestic infelicity may have contributed materially as a predisposing cause to the untoward event.

STANLEY HOSPITAL, LIVERPOOL.

CASE OF CARBOLIC ACID POISONING.

(Under the care of Dr. COSTINE.)

For the following notes we are indebted to Mr. E. R. Williams, M.R.C.S., junior house-surgeon:—

E. H—, a young girl of seventeen, was admitted on July 21st, having, it was stated, two or three hours previously taken poison, the nature of which, in spite of several awkward and futile attempts at its pronunciation, it was impossible to learn. Her condition was one of extreme danger. She was completely anæsthetic, her muscles relaxed, eyelids closed, pupils dilated and inactive, skin cold and clammy, with large drops of perspiration like beads running down the cheeks, temperature manifestly lowered, respiration feeble and shallow, the pulse at the wrist imperceptible, and the action of the heart feeble and intermittent. From this extreme state of collapse, by means of subcutaneous injections of ether, galvanism, etc., she gradually recovered. Careful examination of the dress, hands, lips, breath, mouth, and fauces revealing nothing as to the nature of the poison, it was deemed advisable to give her one-eighth of a grain of apomorphia subcutaneously. In fifteen minutes she expelled with a gush about five ounces of a dark-colored liquid, smelling strongly of carbolic acid. Having now ascertained what the poison was, the stomach-pump was used, and some olive oil injected. This she soon vomited, together with a little more of the same dark-colored fluid. The urine passed was of a dark-brown color and gave the usual tests for carbolic acid. The fæces were also of a dark color. With the exception of some soreness of the mouth and throat, together with a little pain in the epigastrium, all of which were relieved by appropriate medicines, she recovered without a bad symptom, and on the fifth day after admission was discharged. To complete the history of the case, it may be added that having had a quarrel with her lover she determined to destroy herself, and with that intention took a pennyworth, about one ounce and a half, of the common crude carbolic acid.

CITY OF LONDON HOSPITAL FOR DISEASES OF THE CHEST.

MOVABLE TUMOUR IN THE ABDOMEN, SIMULATING MOVABLE KIDNEY; NECROPSY; DISPLACEMENT OF LIVER.

(Under the care of Dr. EUSTACE SMITH.)

For the notes of the following case, which is of considerable interest from a diagnostic point of view, we are indebted to Mr. T. H. Waller, M.R.C.S., L.R.C.P. Lond, resident medical officer.

J. S—, aged thirty-four, married, was admitted on June 4th, suffering from advanced phthisis and laryngitis. While in hospital she drew attention to a lump in the right side of her abdomen, which she had noticed for the first time after her last confinement three years previously. It caused her no inconvenience whatever—no pain except on pressure, and then very slight. She had noticed that it often shifted about from one place to another.

On examination, a tumour was felt in the right side of the abdomen, below the margin of the ribs,

with the following characters: It was solid, firm, oval in shape, with the long axis parallel with that of the body, and easily movable. When the patient lay on her back, the tumour could be grasped between the thumb and fingers in the right loin, but when she turned on her left side the tumour could be felt in the middle line of the abdomen, returning to its original place immediately the patient lay on her back again. The right kidney could not be felt positively in its natural situation. There was no dulness below the edge of the ribs in the natural position, but when the tumour was pushed forward to the anterior surface of the abdomen, it was found to be dull. The urine was examined several times, and always free from albumen, but contained latterly an abundant deposit of urates. There was no history of any urinary trouble. The tumour was thought undoubtedly to be a "movable kidney." The patient died on July 25th.

Necropsy.—The right lobe of the liver extended three inches and a half below the level of the ribs, reaching downwards just below the highest point of the crest of the ilium; from its emergence from under the ribs downwards, it nowhere measured more than an inch in thickness. Following the same mode of examination, the movement of this part of the liver corresponded in every way with what had been felt during life: when grasped between the thumb and fingers this part of the liver was folded upon itself, thus giving the tumour the oval shape, and the resemblance to that of the kidney. When removed the liver weighed 48 oz., and was healthy. The gall-bladder contained three gall-stones, the size of ordinary marbles, with several well-marked smooth facets on each. The gall-bladder was full, but not distended; the duct leading from it was occluded, not admitting the largest end of a post-mortem needle further than its entrance. The right kidney was in its natural situation, and healthy.

CASHEL UNION HOSPITAL.

NECROSIS OF SKULL FROM TERTIARY SYPHILIS.

(Under the care of Dr. LAFFAN.)

THE subjoined case possesses some interest from the guarded prognosis which it suggests in cases of syphilis, and from the obvious failure of mercury to prevent the worst manifestations of the disorder years after the original disease was contracted.

D. C—, a smith by trade, aged thirty-four, was admitted in March, 1878, with an abscess in the right ankle. He contracted syphilis in 1871, for which he was mercurialized. In 1875 syphilis attacked him again, for which he was treated with mercurial fumigations. There was some history of scrofula, but not a very clear one. He got occasional rigors when the weather changed, and these continued. They were accompanied by sleepiness and loss of appetite. Pulse 160; tongue brown and dry; head hot, but without pain; pupils contracting and sensible to light; noise in the ears.

July 29th, 1882.—A round piece of frontal bone exposed and necrosed over right eye, bone also exposed over left eye, with pus flowing freely from both places; sight unaffected; taste on tongue; occasional vomiting; some stupor present, which is more marked from time to time; some injection of conjunctiva. A marked rigor assailed him this day week and continued on and off up to the present. He had a horrible fetor from the breath, which continued to the end.

Aug. 5th: Temperature 96°; pulse 112; respiration 40. Bowels moved four times; the patient's sputum is of a bloody color. He is perspiring a

great deal; appetite very bad; appearance dull and wasted. He had a rigor at 8.30 p.m. yesterday; and a large swelling was observed on the top of his head, which broke and discharged a great quantity of fetid pus.—6th: Pulse 112; respiration 40; temperature 102°. He perspired a good deal; the bowels moved three times; he slept very little; appetite bad.—7th: The patient has had no sleep, took his drinks. Was restless for some hours before death, and had three motions of the bowels.

The purulent discharge continued to flow freely till about three hours before death, and was intermixed with a little blood. The stupor or hebetude went on till half an hour before death. This hebetude, which had gone on increasing from the commencement of the attack, was at no time so deep but that when at its worst he could reply consciously to questions. There was no local paralysis except a slight one of the face, the muscles being drawn to the right side. Two days before death there was a little delirium. Half an hour before death he asked for a drink. He died comatose on August 12th.

CITY OF DUBLIN HOSPITAL.

MR. HENRY GRAY CROLY'S CLINIQUE.

The following cases were recently under Mr. Croly's care, and present many points of interest:—

Cellulitis of the Neck.—A man, about thirty-seven, applied on July 3rd with a large tumour of the right side of the neck, which had been growing for the past six months. The posterior part of the tumour was extremely hard, and a question arose as to whether it might not be a case of medullary sarcoma. Mr. Croly used an exploring needle, which permitted a muco-purulent fluid to escape, and the man was taken into the theatre and there etherized for further operative measures. A free incision was made in the lower and anterior part of the neck, and the cervical fascia divided on a director, thereby allowing a free discharge of blood and pus. In making the necessary incisions in the neck to divide the cervical fascia, and thus to relieve tension and give exit to the infiltrated fluids, Mr. Croly sketched on the patient's neck before operation what he called "lines of safety" and "lines of danger," and which were described by him in an excellent monograph on Cellulitis, published in 1873. The lines of danger are those in the direction of the external jugular vein, which passes from the angle of the jaw downwards and outwards across the sterno-mastoid; and another line corresponding with the carotids in their course upwards and backwards.

Burns of the Head and Face from a Gas Explosion, caused by Flint and Steel.—This patient, a laboring man, received his injuries in a very singular manner. He was using a pickaxe in one of the Dublin streets when, on making a heavy blow, his pick struck on a large flint, and at the same time penetrated the main gas-pipe in the street. The fire struck from the flint ignited the gas which escaped, and the workman received severe burns about the head, face, and left arm.

Acute Edema of Scrotum.—A boy aged twelve, lately came to the hospital with acute oedema of the scrotum. About four days previously he fell on a spike of a railing, which explained the inflammatory condition of the part. Mr. Croly pointed out the similarity which existed in its appearance and that which usually presented itself in the extravasation of urine. The ether spray having been applied, Mr. Croly made an incision on one side, and gave exit to some pus and fluid.

STATION HOSPITAL, CAWNPORE, INDIA.

CASE OF HYDROPHOBIA; NECROPSY; REMARKS.

(Under the care of Surgeon S. J. RENNIE, A.M.D.)

J. B.—, Private 2nd Scottish Rifles, was admitted to hospital on Feb. 17th, 1883, complaining of pain and stiffness in his right shoulder, and spasm of the muscles of the glottis on swallowing liquids. There was no history of a bite from a dog or any other animal. The spasms were of short duration, and at first did not occur except when the patient attempted to swallow liquids, but afterwards the slightest breath of air or the application of the hand to his chest immediately produced a most distressing state of affairs. During the paroxysms great protrusion of the eyeballs was noticed. There was great mental excitement and a very heavy look about the face. The temperature was normal, and the bowels were open. He took his food well, but immediately he attempted to swallow liquids the spasm returned.

On admission, he was ordered a saline purge, and at night he had one drachm of solution of hydrochlorate of morphia. He did not sleep much.—18th: Ordered twenty minims of tincture of nuxvomica, fifteen grains of bicarbonate of potash, fifteen grains of bromide of potassium, and ten minims of tincture of opium three times a day. The spasms still continue. Bowels have been opened; temperature normal. Takes his food well, which is the regulation low diet. In the evening his tongue was covered with a white fur, and the pain in the shoulder severe. Ordered compound camphor liniment to shoulder, and ten grains of Dover's powder to be taken at once. Temperature 99°; pulse 90, full and strong. 19th: Seemed a little better; ordered blister to shoulder; spasms not so frequent; to continue medicine. Evening: Much worse. Temperature 100°; pulse 112, full and bounding. Ordered twenty grains of chloral hydrate and twenty grains of bromide of potassium at once. Some delirium had now showed itself. The draught was repeated at 9 p.m., when he was very violent, and presented all the symptoms of the hydrophobic state. His face was flushed and his eyes sparkling, and he was constantly attempting to expectorate the viscid mucus that hung about his gums and teeth. He struggled in his fits, and bit and struck at everyone who came near him. The draught, which was repeated three times, had no effect on him, and it took four strong men to constantly hold him. The slightest breath of air or motion in the room was sufficient to bring on a fit of wild fury. Towards morning he seemed exhausted, and the fits became less frequent.—20th: To-day he is very delirious, but has frequent lucid intervals, in which the poor fellow begs people not to come near him for fear he may hurt them. He also seems to feel acutely his position. His constant attempts at expectoration are very distressing to him, and the saliva has to be frequently wiped from his mouth. He took some milk and beef-tea, but refused water, the sight of which at once produced a convulsion. His head was shaved and an ice bag applied to both head and spine. 10.50 a.m.: Patient has just died suddenly during a convulsion, which was apparently less severe than usual. There was no previous sign of any marked exhaustion. He had suffered considerably the previous year from acute rheumatism and also from ague, and had just returned from the hills, where he had been sent for his health.

Necropsy, five hours after death.—Body well nourished; rigor mortis marked; there was considerable cutaneous hypostatic congestion; no marks or scars of bites discoverable. Right shoulder es-

pecially examined. Brain: Weight 2 lb. 11 oz.; much congested; some lymph was deposited along the edges of the longitudinal fissure; arachnoid vessels congested; substance of brain firm; puncta vasculosa marked, showing congestion; no fluid in ventricles. Spinal cord: Vessels much congested; marked softening of substance in dorso-lumbar region, with inflammatory thickening of membranes; the softened spot was an inch and a half in length, and opposite the last dorsal vertebra; the cord was almost entirely disintegrated at this place, the posterior columns suffering most. Lungs: Very much congested, and exuding frothy mucus on section. Liver: Weight 3 lb. 15 oz.; also very much congested. Heart: Weight 11 oz.; auricles empty; both ventricles contained dark fluid blood; valves healthy. Spleen: Weight 8 oz.; on section firm, but filled with dark grumous blood. Kidneys: Right 5 oz.; left 4 oz.; both intensely congested, but otherwise healthy. Bladder: Moderately distended. Stomach: Congested; intestines contained no entozoa.

Remarks.—There was no history of a bite from a dog or any other animal. The man, however, was one who was always out shooting, and also kept pets, and may have fondled a rabid animal, or may have shot a mad jackal or fox, and having torn his hand with a thorn may thus have become inoculated during the process of skinning. At any rate, the symptoms were those of hydrophobia, which was borne out by the post-mortem examination, the appearances being similar to those which were observed in two cases of undoubted hydrophobia which I have had the opportunity of seeing—viz., softening in the dorso-lumbar region with congestion of the membranes, and also general congestion of all the organs of the body. The case was a peculiar one from the first, owing to the earlier symptoms being marked by the intense pain in the shoulder, but the subsequent development of the disease left little doubt as to its true nature, in which Brigade-Surgeon Carter and Surgeon-Major Irving, who saw the case in consultation concurred.

WORCESTER GENERAL INFIRMARY.

CASE OF COMPLETE SUPPRESSION OF URINE LASTING FIFTY-THREE HOURS, FOLLOWED BY CYSTITIS; RECOVERY.

(Under the care of Mr. HYDE.)

For the following notes we are indebted to Mr. M. B. Shirley, house-surgeon.

John —, aged fifty-eight came to the casualty-room, at 10 A.M., on May 18th, suffering from stricture of the urethra. He had suffered from stricture for the last twenty years, and had had it frequently dilated surgically. Lister's sounds, from No. 9 to No. 12, were passed, and the patient refusing to stay in the infirmary was allowed to go home. About 3 P.M. he was brought back, having had a rigor in the street.

On admission he complained of great pain in the lumbar region: temperature 102°; pulse quick and full. He was put to bed; brandy was given, and warm bottles applied.

May 19th, 8 P.M.: He has passed no urine since his admission.—20th, 10 A.M.: He has passed no urine and is drowsy. Pulse slow and full; temperature 97°. His tongue brown and furred. The catheter drew off two ounces of almost pure blood. The bladder was washed out with a solution of carbolic acid, one in 100. He was ordered quarter-grain doses of pilocarpine with half a drachm of sulphate of magnesia every three hours. Loins dry cupped. 8 P.M.: The patient perspired freely

during the day; still no urine passed. The catheter drew off two ounces of urine, which deposited pus. The bladder was washed out. The patient is better. To continue the medicine.—21st, 10 A.M.: Passed a little urine; still perspiring profusely. Medicine to be continued.—22nd, 10 A.M.: Has passed twenty ounces of urine during the last twenty-four hours, which deposited pus. The bladder was washed out with a weak solution of salicylic acid. The medicine stopped.—23rd: Sixty ounces of urine passed. One ounce of infusion of buchu ordered three times a day.—27th: The bladder has been washed out twice daily since the last note with a solution of salicylic acid. The urine is now passed in large quantities naturally. The cystitis is quite disappeared. The patient expresses himself as quite well.

QUEEN'S HOSPITAL, BIRMINGHAM.

TWO CASES OF ULCERATIVE ENDOCARDITIS WITH BRIGHT'S DISEASE, IN ONE OF WHICH ULCERATION THROUGH THE AORTA TOOK PLACE.

(Under the care of Dr. HUNT.)

For the following notes we are indebted to Dr. Leslie Phillips, late house-physician.

CASE 1.—Jessie G—, a dressmaker, aged twenty-one, was admitted on November 28th, 1882. She had scarlet fever when young. Eight weeks before admission she had an ulcerated throat, attended with enlarged cervical glands, followed by rheumatic fever. About ten days before admission the feet began to swell. She had had headache and vomiting.

On admission there was marked anæmia, with slight œdema of feet. The heart's apex-beat was diffused and its dulness increased upwards to the third cartilage; there was a systolic bruit at the apex and also at base, the latter being of maximum intensity in the pulmonary area. There was visible pulsation of the neck vessels. There were no abnormal pulmonary signs. The morning temperature was 101° F.; the evening temperature was also 101°. Pulse 96; respiration 29. She passed 112 ounces of reddish urine, specific gravity 1003, containing a cloud of albumen when boiled. The next day the urine was smoky, sp. gr. 1010, and contained a third of a column of coagulum. The microscope showed numerous leucocytes, blood-cells, blood-casts, and cellular casts. There was no tenderness on palpating the kidneys. The fauces were congested. There were no hæmorrhages in the fundi of the eyes.

Dec. 6th: The patient has vomited. The temperature has been hectic in its type, rising to 104° in the evening, and falling in the morning to 100°. She has continued to pass large quantities of urine—112, 64, 108, and 90 ounces daily. Pulse dicrotic. On the 13th a temporary improvement was noted. She was stronger than on admission. The next day, however, she was not so well. There were nausea, headache, and tinnitus in auribus. The quantity of urine fell to thirty ounces, and to the end of her disease the quantity did not rise again. Some œdema of feet. To take purgative mixture.—16th: Very ill. Evening temperature 104°. Headache and vomiting.—19th: Has continued very ill; rigor lasting three hours. The anæmia is very profound.—21st: Last two days has had constant rigors followed by sweats. The temperature rises during the rigor. There is a double bruit at midsternum.—22nd: Worse. Diarrhoea. Temperature taken at 6 A.M. and 6 P.M. was normal, while at 11 A.M. it was 105°. Urine, twenty ounces, containing two-thirds of a column of albumen coagulum and one-eighth of a column

of pus.—23rd: Worse; vomiting constant, rigors occasional, diarrhoea continued. Sleepless, constantly moaning; cough appeared with pneumonic signs at the right apex. During the next two days the condition of the patient was very painful, there being extreme dyspnoea, præcordial pain, asomnia, desire for death, and delirium. The thermometer did not rise above normal. She died on the 26th.

With regard to treatment, among other drugs she took two grains of salicylate of quinine every hour from the 20th to the 24th, but without improvement. During the last three days the greatest benefit was derived from giving her five minims of the solution of hydrochlorate of morphia, with one minim and a half of the solution of sulphate of atropine occasionally. After each dose the breathing became easy and the patient comfortable, remaining so for some hours.

Necropsy.—Body moderately anasarous; surface waxy. The kidneys were large, whitish, and lobulated, the capsule easily stripping; the two weighed 14½ oz. There was no pyelitis or cystitis. The liver was fatty, and weighed 57 oz. There was some passive effusion into the abdomen and into both pleuræ. The apex of the right lung was hepatized. The heart was hypertrophied, weighing 12 oz. One segment of the mitral valve was sclerosed. On one segment of the aortic valve was a peculiar condition, which was regarded as a stage of ulcerative endocarditis. The valve was one-eighth of an inch thick, almost as hard as cartilage, irregular on the surface, and of the same color as the aorta. One of the other segments was also slightly affected. There were none of the friable, discolored, pendulous vegetations usually present in ulcerative endocarditis.

CASE 2.—Harry P.—, aged thirty, a brass-worker, was admitted on January 23rd, 1883. One sister died of diabetes. The patient had rheumatic fever fifteen years ago, and ever afterwards had had palpitation and dyspnoea on exertion. He began to feel ill six months before admission. He had thirst and frequent micturition, with passage of tea-colored urine. There was vertigo, but unaccompanied with headache or vomiting. Five months ago there was swelling of the feet.

On admission there was some œdema of the legs; anemia was marked, the face being puffy and pasty. There was vertigo and pyrexia. The evening temperature was constantly 103°; the morning temperature varied from 100° to 101°; pulse 108; respiration 18. There was intractable asomnia; later in the disease this gave place to polysomnia. He passed large quantities of urine (62, 56, 51, and 112 ounces daily); neutral, specific gravity 1010, containing a cloud of albumen and no sugar. Microscopically, there were cellular and granulo-cellular casts, with blood-corpuscles. The impulse of the heart was indistinct within the nipple line; the dullness was increased transversely, and upwards it began at the third cartilage. There was a systolic blow at the apex and also in the aortic area, and there was an accent on the second sound.

February 15th: Asomnia, pyrexia, polyuria, and thirst have been the principal symptoms. Pulse dicrotic.—17th: Anæmia very marked; insomnia has given place to drowsiness. Evening temperature 104°.—23rd: There are no retinal hæmorrhages. For the last few days rapid breathing has been a marked feature, without chest signs. Respiration 36 during sleep.

March 1st: Anæmia still greater; sleeps night and day. Respiration 48.—2nd: Distinctly worse; vomiting; is deaf.—3rd: It is with great difficulty that he can be made to understand or answer questions; a slight trace of albumen in the urine.—

6th: Failing gradually; passed evacuations in bed.—7th: Delirium; purpura appeared on the hands.—8th: Double murmur at the base of the heart, and also a sound like pericardial friction; he lies on his back breathing heavily, forty times a minute; mostly sleeping; is obviously dying, as he has been for six days past. He died comatose on the 9th.

Necropsy.—The kidneys "large white," together weighed nineteen ounces. The spleen contained two old infarctions and weighed twelve ounces. The liver large and fatty (five pounds six ounces). Each pleura contained about half a pint of blood-like fluid, which the specific gravity (1038) showed was not merely bloodstained serum. Two ounces of fluid blood in the pericardium, and a considerable quantity of clot and whisked fibrin, evidently the result of extravasation going on while the heart was beating. This clot was situated around the base of the heart, within the pericardium, and probably caused the friction sound heard the day before death. No pericarditis. The heart weighed thirty ounces, and was the seat of extensive ulcerative endocarditis affecting the left cavity valves. From the mitral valve depended large and easily detached friable and pigmented pendulosity. The process also extensively affected the auricular endocardium, while the aortic valves were similarly affected. Above the situation of the aortic valves, in the aorta, was extensive ulceration; eating its way through the coats of the vessel obliquely upward, it had perforated at the posterior aspect of the aorta between that vessel and the right pulmonary artery, near the reflection of the pericardium, but its exact relations with that reflection cannot be precisely stated. (This heart has been forwarded to the Royal College of Surgeons museum.)

Remarks by Dr. PHILLIPS.—In many respects these two cases ran in parallel lines, a recapitulation of which may be of use. In both there were hectic fever, progressive anemia, great thirst, asomnia, dyspnoea, vomiting, and the passage of large quantities of albuminous urine, coexisting with the signs of cardiac disease. In both the death-bed scene was prolonged. In the first case were superadded, recurrent rigors, angina, and diarrhoea, with death from pneumonia. The death in the second case was due to gradually deepening coma. In neither case were retinal hæmorrhages observed, but it must be stated that no examination was made late in the disease; and, as in the second case purpura appeared on the hands a day or two before death, a similar purpuric condition may have been present in the retina. The blood in the pleuræ in this case was attributed to the vascular (purpuric) condition; that in the pericardium probably leaked through the perforation in the aorta, and this latter theory finds confirmation in the interesting fact that a double pericardial friction sound was heard at the base of the heart the day before death, and that after death a churned mass of fibrinous filaments and blood was found occupying this situation. This case plainly shows that hæmorrhage slowly taking place into the pericardium, as from an aneurism, may give rise to a pseudo-friction sound. In one case the ulceration took place on old standing valvular disease; in the other it immediately supervened on the rheumatic endocarditis. Some writer has insisted that in ulcerative endocarditis an important diagnostic sign is that the physical signs may show the valvular lesions to be rapidly progressive; this was well observed in the first case, in which an obstructive basic bruit soon became double. The presence of ear symptoms in both cases is striking—tinnitus in one, and deafness in the other. I must acknowledge the courtesy of Dr. Hunt in placing these cases at my disposal for publication.

Editorial.

INNERVATION OF THE HEART.

THE study of the evolution of function, more especially that of contractility, is the study of a varying polarization. Primordial protoplasm is completely depolarized but potentially capable of any variety of specialization. Cardiac physiology bids fair to become perhaps the most debated territory of all physiology. If any proof of this were wanting, it would be furnished by a careful reading of a philosophical paper forwarded to us by W. H. Gaskell, F.R.S. The views held by physiologists upon many points connected with the innervation of the heart have been too exclusively based upon observations made upon a single type of heart—viz., that of the frog. It is therefore advisable to control and supplement these experiments by corresponding elaborate series of observations upon the hearts of a large number of other animal types, and in this way to trace the evolution of function in the same fashion as the morphologist tracks that of structure. The paper to which we refer is divided into four parts, each of which deals with a definite portion of cardiac physiology. Lucidity is thus secured at the cost of some brevity and simplicity. Gaskell believes that the cardiac functions are the result of a specialization of muscular tissue. No structural nervous system is necessarily required in this view of the matter. The keynote of the peculiarities of the cardiac muscle consists in its structural position, intermediate between unstriated and striated muscle fibre. Muscular tissues exhibit three different modes of responding to stimulation according to their structure. These modes may be expressed by saying that certain muscles possess essentially the power of "tonic contraction," others the power of "rhythmical contraction," and others that of "rapid contraction." In the striated muscle of vertebrates rapidity of contraction is most highly developed, tonicity is rudimentary, rhythmic action is still more rudimentary. In cardiac muscle rhythmic action is most conspicuous, rapidity of contraction is well marked, and tonicity is excellent. In unstriated muscle tonicity is most prominent, rhythmic action is well marked, rapidity of contraction is most rudimentary. All examples of a varying polarization. Rhythmical contraction may thus take place in the absence of structurally demonstrable neural apparatus. Unstriated muscle, as found in the ureter and in the veins of the bat's wing, is capable, under the influence of the mechanical stimulus of distension, of contracting as rhythmically as the apex of the frog's heart. But we have also evidence that the more highly developed striated muscle fibres are capable of rhythmical contractions under the influence of a constant stimulation, whether electrical or chemical. Schönlein

has proved this, especially in the case of the striated muscles of the invertebrata, which contract rhythmically upon stimulation by a weak interrupted current.

Speaking of the spontaneous rhythm of the different parts of the heart, and of the heart as a whole, Gaskell arrives at the following law: the power of independent rhythmical contraction decreases regularly as we pass from the sinus to the ventricle (frog, tortoise). Between the automatic rhythm of the sinus and that of a muscular strip removed from the apex of the ventricle no hard-and-fast line can, however, be drawn; the differences are of degree, not of kind.

As students of physiology know, the rhythmic action of the heart is usually attributed to the influence of the nervous ganglia, which have been found in its substance. The causes which regulate the sequence of the contractions of the different heart cavities are likewise believed to reside in these coördinating centres; but these positions are attacked by Gaskell. He shows that for the heart of the tortoise the proper sequence can go on even after section of the intercardiac nerves, which in this animal lie under the pericardium only, and in the junction-wall between the two spongy-looking auricles. He says the ventricle contracts in due sequence with the auricle because a wave of contraction passes along the auricular muscle and induces a ventricular contraction when it reaches the auriculo-ventricular groove. Muscular rings have been demonstrated to exist between the sinus and auricle, and between the auricle and ventricle. These are said to be amply sufficient to account for the passage of the contraction from the sinus to the auricle and so forth, without the necessity of invoking the presence of ganglion cells. At the same time an explanation is afforded of the natural pauses between the contractions of the different cavities because the muscular rings are intermediate in structure between the sinus and the auricular muscles, and the rate of their power of conduction is less as compared with the other muscles.

The action of the cardiac nerves on the rhythm, force, and conductivity of the heart muscle is next considered in detail. Just as the rhythm and the sequence of the heart's action are found to be independent of the neural system, so in this department Gaskell believes that the principal factor in the results obtained by nerve stimulation belongs to the muscle. In the tortoise the nerve fibres supplying the muscular fibres of the sinus, which by their alternate contractions originate the rhythmical beats of the heart, run almost exclusively in the right vagus nerve. Stimulation of the vagus may slow or stop the rhythm; after the standstill thus brought about a distinct acceleration is often observed. When the sinus of the heart of the tortoise is removed, the independent rhythm of the rest of the heart (which sets in after a more less long preliminary standstill) may,

according to Gaskell, be arrested by stimulation of the intercardiac nerve. This is a new fact in the physiology of the heart of the tortoise.

With regard to the force of the contractions, stimulation of the cardiac nerves is only able to diminish the power of the auricular contractions; the ventricular contractions are never directly influenced in the slightest degree. Further, although the contractions of the auricles are always markedly diminished in strength, yet they are increased in force *after* the end of the stimulation.

With respect to the conduction power of the muscular tissue, it is believed that the cardiac nerves are able both to depress and exalt this attribute of the auricle of the frog and the tortoise. Again, as regards the sequence of the contractions, the cardiac nerves are found to be able both to stop and to aid this phenomenon. When, for instance, an artificial partial block is produced (either by section or the clamp) the most striking effect of nerve stimulation is the removal of that obstruction by completely repairing the conduction power. But stimulation of the nerve when the natural pause only exists is provocative of prolongation of that pause, which may lead to complete standstill. Nevertheless the action of the vagus nerve is of the same kind throughout, and the different effects produced are not due to the action of different nerve fibres possessing different properties, but rather to the action of the same kind of nerve-fibre upon different attributes of the cardiac muscular tissues. Thus the nerves supplying the red and the white muscles of rabbits are not supposed to be different to other motor nerves, yet their stimulation produces very different results, owing to the differences which exist between the red and white muscles themselves. In precisely the same way the same kind of nerve-fibre will bring about different results in the heart according as the muscle fibres upon which it acts are specially engaged in the initiation of rhythmical contractions, in the conduction of a contraction wave, or in the production of strong and rapid contraction.

Although the initial effect of the vagus is to depress some function of the heart muscle, yet its final and most enduring power is to exalt, intensify, and repair that function. Thus, although it slows rhythm, yet its stimulation makes the rhythmical power last longer than it otherwise would, and makes the heart beat with regularity when it was previously irregular; although it reduces the force of the contractions, yet its ultimate effect is to improve and sustain the contraction force; although it may reduce the conduction power, yet in the end it completely repairs that power. For these reasons Gaskell regards the vagus as the trophic nerve of the heart. He shows also how the weak interrupted current has the same effect on the force of the contractions of a strip of cardiac muscle as the vagus nerve has upon the whole auricle or ventricle; and, further, how

atropin has the same effect upon the action of the interrupted current as upon vagus action. The resemblance between the action of the vagus nerve and the weak interrupted current upon the conduction power and the contraction force, is in all cases very striking. Gaskell thoroughly believes that the weak interrupted current and atropin act upon the muscle primarily in the above instances. Atropin improves the rhythmical power and the conduction power in the same way as the contraction force, such an improvement being of stable character, though not necessarily lasting. On the other hand, muscarin ought to depress every function without preventing the possibility of a limited amount of improvement of that function. Atropin influences not only the muscular tissue, but also the nervous structures of the heart in such a way that neither the direct action of the interrupted current nor stimulation of the vagus nerves is any longer able to produce their usual effects upon the various functions of the cardiac muscles. The views put forward by Gaskell will necessitate a revision of the opinions at present held in respect of the action of a large number of cardiac poisons. The doctrines here taught are those of a thorough-going myologist.

BODY AND WILL.

DR. HENRY MAUDSLEY'S new book, "Body and Will," is wondrously clever as a speculative essay on the subject of which it treats, but it is a mistake: a mistake in policy; and a mistake—a very grave one indeed—in science. The author is held in such very high esteem by the specialty to which he belongs that it may seem disloyal to give expression to this opinion; but the time has arrived when it is desirable to speak out, and very plainly too, on the subject of the new departure in physiological psychology of which Dr. Maudsley is regarded, and probably regards himself, as the originator. If we describe his gift as that of cleverness rather than wisdom, it is in no disrespectful spirit that we make the discrimination. Dr. Maudsley's philosophy as a whole—and this book, which may be taken as its latest embodiment, in particular—must be characterized as a peculiarly aggressive development of Agnosticism. His supreme pleasure in literature would seem to be the sad delight of demolishing the hopes and beliefs of his fellow-mortals. He is never weary of reminding them of their mortality, and never so happy as when he has twisted a coil of argument around the tortured consciousness and convinced himself and his reader—for the moment at least—that there is nothing to look for beyond the grave. At times he indulges in this grim humor to the extreme; for example, when he argues that "To us who are alive it may seem incredible that death can be the adequate end of such a long succession and such a vast complexity of life; but it is incredible only because we are alive

and conceive things according to our own measure; it will be more credible to each of us when he is nearly dead, and not incredible at all when he is dead." According to Dr. Maudsley's view of matters, when a man is dead there is an end of him, so that the concluding remark, which must needs give offence to many, has not even the excuse of a paradox. The quotation with which the book before us closes is a fair epitome of the lesson which the author would teach: "All that which is past is as a Dream; and he that hopes or depends upon Time coming, dreams waking."

We say the book is a mistake of policy, because it is not either prudent or justifiable for any man to make a demonstration against the accepted view of things unless he has something better—at least in his own estimation—to substitute for that which he would sweep away. Now, no thoughtful person can read Dr. Maudsley's writings without feeling that the mind of their author is unsatisfied if not unstable. In every page there are indications of the turmoil which is going on within it. He asserts his avowed convictions with more vehemence than belongs to calm persuasion, and he attacks those who differ from him with too much bitterness and impetuosity for a philosopher who is sure of his ground. Dr. Maudsley really ought to feel sorry to be driven to the humiliating conclusion at which he thinks he has arrived; and seeing that it is not a gospel of hope or encouragement that he has to preach, should have some pity for his kind and hold his peace. The utmost consolation he has to offer the world is that which he states thus concisely in the *Pathology of Mind*:—"So long as man has organic viscera he will have emotion enough, whatever his beliefs and disbeliefs may be: there need be no fear that he will lose his emotional nature and become a hard intellectual machine when he no longer puts up prayer or offers sacrifice to a personal God of like nature and passions with himself." Meanwhile, as he remarks in another place, "Herein lies the imputable mischief of prayer, that it is an imbecility of the will." Obviously thoughts like these—even if they be truths to the thinker—are not worth expressing; nor, as a matter of fact, would they be expressed if he were as well assured of their truth as he would have us believe him to be. Dr. Maudsley is *not* sure of his ground. He contradicts himself at every twist and turn, and it is well for the sake of the young and inexperienced in scientific life who may be captivated by his forcible and most excellent diction that the fact should be stated. In the preface to this new book he anticipates the objection of "adepts in the schools of high mental philosophy," and in justification of his view pleads that he has been all his life "dealing with mind in its concrete human embodiments." According to the author, mind can have no existence except in the concrete, so that the explanation offered is obviously unnecessary. Even in this matter, however, Dr. Maudsley

is not accurate. It is evident in the present, as in other of his works, that the concrete mind with which he has been dealing all his life is simply his own individual consciousness. What he describes as the phenomena of brain-function not his own he has derived from other writers, and in the use he makes of the material taken from divers sources he is either not precise or not intelligent, as witness the quotations and paraphrases of passages from Scripture, and from the writings of many divines, with which this and his other works are profusely illustrated. That this must be the conclusion at which even his most friendly critics will arrive there can be no question. For example, his view of the future of the human race, a future of degeneracy and of return to worse than primeval savagery, is nothing more than a misapplication of Herbert Spencer's hypothesis of "dissolution," at first sight barely recognizable. Dr. Maudsley is distressed and distresses his readers with alternating attractions and repulsions between the two schools of philosophy and science. So far as the reader can form any clear estimate of the precise position of the author's consciousness, it would seem to be like Mahomet's coffin, suspended between heaven and earth, neither able to soar to the one place of rest, nor to bury itself resignedly in the other. For the present the author seems inclined to fall back on the oldest form of faith and pay homage to the Sun. "For us men and for our salvation, the earth and its sun are all in all, but in the universe and its evolution new heavens and new earths may be natural incidents;" and therefore, while denouncing all confidence and hope in the future, he makes the reservation that, "It is perchance a cosmic instinct of the matter of which we are constituted," this "hope and conviction of a future realization of lofty ideals."

Our principal objection to Dr. Maudsley's reasoning is its notable lack of relation to the practical. No writer on psychology, as viewed from a physiological and pathological standpoint, makes more frequent allusion to, or lays greater stress upon, the Consciousness than he does; and yet there is no writer, with whose works we are acquainted, who shows less practical acquaintance with the facts of Consciousness, as evidenced by the action of minds other than his own. In illustration of our meaning, take the conception the author has formed of the mental act or state of the suicide. "From a purely psychological point of view," writes Dr. Maudsley, "it [that is, suicide] must be acknowledged the most momentous example of Free-will on human record." He assumes that the person about to commit suicide is convinced of the existence of a life after death, with an alternative of joy or woe, convinced also that suicide will precipitate him into an abyss of endless suffering, but "the unhappy person nevertheless recklessly perpetrates it when his misery on earth is greater than that which he believes he

is able to bear." Dr. Maudsley does not perceive that the state of mind he is describing is as far as possible from one of "free will." The man who, because he has more misery now than he can bear, deliberately and knowingly performs an act which he is convinced will "precipitate him into an abyss of endless suffering," must of course be mad! The author's love of paradox has led him astray. This is how he argues. "Against it [suicide] there is every motive that can influence a conscious being, so that the act is, *quid* consciousness, the most wonderfully illogical act of which anyone can be guilty: either a stupendous example of free will or a *reductio ad absurdum* of the doctrine." Obviously it is not either. The illogical nature of the act is proof that the intelligent consciousness cannot be sanely concerned in its determination; and it is certainly no *reductio ad absurdum* of the doctrine of free will to say that a man may be insane! As a matter of fact, apparently not observed by Dr. Maudsley, the sane and conscious suicide is not "assured that suicide will precipitate him into an abyss of endless suffering." He inclines rather to Dr. Maudsley's own view—namely, that death is the end of life. It is because he hopes and half believes this strange doctrine to be sound, that he dares the chance of escaping from the misery on earth which he is unable to bear. The logical outcome of this doctrine must be that on the whole suicide is about the most rational act a miserable man can perform. We expose the method and denounce the doctrine—the one is faulty, the other bad. Dr. Maudsley has clearly forgotten that the minds with which he has had to deal have been morbid, and, forgetting this, he has mistaken the product of mental disease for the outcome of a sound and intelligent consciousness. This misconception runs through the whole of Dr. Maudsley's writings, and it is conspicuously evident in the new volume from his pen. The mistake of the abnormal for the normal underlies the whole essay, and, when it does not vitiate, weakens the force of, the argument. It appears at the very outset, where the author bewails the want of a "Diabolometer or Satanometer," to measure the evil influences exerted on the mind and opposing the good influences, which he summarizes, as set forth by Dr. Isaac Barrow, the divine, and then characterizes as "a stupendous array of motives, which it is a standing wonder anyone ever withstands, seeing that they are wielded by the power of Omnipotence and guided by the insight of Omniscience." In Dr. Maudsley's estimation a free will choice of good in preference to evil, or the converse, would be an act of insanity. This is what his reasoning amounts to. "The person who answers best, who alone answers near, to the metaphysical definition of free will is the madman." The normal human being is, for the author, an organism more or less easily worked upon by those influences which he conceives to

be the factors in the production of conduct and character. Education is "manufacturing"; and each act of volition—he does not like the idea of an existing and continuous Will—is the resultant of divers forces operative at the moment, and conditioned by the character, inherited and acquired, of the organism, upon and through which these forces act. The odd part of the business is that, while Dr. Maudsley reduces man to this level and makes him a mere creature of circumstances, he asks: "Is it not obvious that, if sane men possessed free wills, they, like the madman, would be free from responsibility, since their wills would act independently of their characters, just as they listed—not otherwise than as a wayward wind was once supposed to blow capriciously 'where it listed'—and that no one would have much, if any, motive left to try to better his character?" The covert sneer at the words of Him who talked with Nicodemus notwithstanding, how can man be responsible if he is nothing more than a manufactured recording apparatus? Albeit "Body and Will" is, as we have said, a clever work, it is a mischievous one, misleading to the student, and unworthy the pen of a Master in Science and Philosophy.

THE GENESIS OF THE BACILLUS TUBERCULOSIS.

THE necessity for a reconstruction of the clinical history of tuberculosis seemed to follow as a logical outcome of Koch's important discovery. And there can be no question that many medical men enthusiastically fell in with the view that phthisis was a parasitic and infectious disease. At the last meeting of the Académie de Médecine, Professor Bouchardat has done perhaps more than justice to these exaggerations, as he regards them, in a communication inspired by the praiseworthy endeavor of seeking to harmonize the known facts of clinical observation with the recent acquisitions of experimental pathology. There can be no doubt that up to the present the doctrine of the contagiousness of phthisis, as demonstrated by the actual record of alleged instances, stands in an overwhelmed minority. M. Bouchardat believes that pulmonary phthisis is originated chiefly under the influence of general conditions determining a state of ill health which has been called *physiological misery*. However, it is argued that the parasitic nature of the disease can no longer be denied. What then becomes the rôle of, and what relation have, the micro-parasites in those cases which are clearly not derived by contagium from without the organism?

The condition of *physiological misery* is essentially characterized by a deficient oxidation and consequent want of calorification, due to insufficient respiration. Certain portions of the lungs have been observed not to expand in proper degree in those who have just become or are about to become the subjects of phthisis. M. Bouchardat

maintains that this local insufficiency is to be found in those in whom tubercles have not yet formed. In such areas the capillary circulation is arrested. At these sites the lymphatic corpuscles placed under abnormal conditions acquire new functions, and amongst others, are metamorphosed into pathogenic bacilli! This, indeed, is a bold return to the doctrine of heterogenesis so strongly upheld by Bastian, and implies not only a spontaneous generation of the micro-parasites, but also of virulent diseases. Beale has believed that particles of protoplasm derived from the living organism may be the germs of disease. And perhaps the view here set forth may supply Dr. Creighton with the most solid basis on which to found his views of the acquisition of specificity by diseases which were originally non-specific. Suppose that we have in the natives of Central Africa to do with a non-contagious suppurating form of lichen, and we wished to know how such an affection became specific and contagious (small-pox). It would not be too much to invoke the presence of the necessary external conditions under whose presiding influence the products of the suppurative inflammation underwent such changes that the inflammatory corpuscles became colonies of bacteria, after the manner advocated by Bastian and now most recently by Bouchardat. The bacilli might then be regarded as veritable spermatie filaments capable of engendering the parent disease from which they were derived. If it be not for some such opinion as this we do not see, although they may exist, on what grounds Dr. Creighton's position becomes intelligible, unless as an ingenious exercise of the scientific imagination. It will thus be seen that the whole question of spontaneous generation would again be opened in some quarters, and that not with a little lease of vitality. Professor Tyndall, in writing recently on the breeding of cholera germs, has remarked very positively and emphatically on the impossibility of our owning any other than the view of contagiousness for the explanation of cases of cholera and typhoid fever. He has spoken of an opposite theory as a dead opinion, which, if it did any good, did much more harm to scientific medicine. Now, although appearances, so to speak, are all against the doctrine of origination *de novo*, yet we hold that it is most scientific not to be so absolute as Professor Tyndall seems to be. He would not deny that spontaneous generation has occurred in long-past ages. And the mind which knows no changes of space and time cannot but conceive that what has once happened may do so again. We say, and say no more than this, that spontaneous generation is a conceivability, and whilst it remains such, it would be folly to shut our eyes and close our ears to attempts to show that the conceivability is something more than legitimate thought.

In thus having pushed to its utmost the heterodox doctrine, we do not desire to forget the actual

teaching of experiment. We unhesitatingly admit that, notwithstanding the intellectual possibilities of the case, the satisfactory proofs of an origination *de novo* have not as yet been given. Nor, judging from the performances of the past, does there seem much hope that the evidences will be forthcoming. And why? The difficulties which surround such a demonstration are so numerous and so complicated; the search after the philosopher's stone is not more so. Conceivably, and more especially in the light of some of the teachings of modern chemistry—we refer to the notion that all the elements may be but remarkable modifications of one element—all other metals may be converted into gold. But who would dare practically to entertain such an opinion with any regard for people's belief in the sanity of his mind! We have thus endeavored to express forcibly the insurmountable objections in the way of establishing the truth of the fascinating doctrine. Possibly in our simile of difficulties we have over-estimated the perplexities which beset those who would prove what most individuals disbelieve.

TUBERCULOSIS IN FOWLS.

THE literature of Tuberculosis is amongst the most extensive of any subject in medical science, and since Koch's discovery of the bacillus contributions to this special department have multiplied at a very rapid rate. The latest and in some respects the most instructive of these essays is contributed by Dr. Ribbert, of Bonn, to the last number of the *Deutsche Medizinische Wochenschrift*, and it consists in a briefly summarized account of some investigations into the pathological anatomy of the tuberculosis of fowls, particularly with reference to the presence of bacilli in the tubercular formations. In the presence of the doubt which still prevails in some quarters respecting the identity of bovine and human tuberculosis—a doubt which is in a fair way of being dispelled if Koch's bacillus is to be taken as the criterion of true tuberculosis—it will excite some surprise and perhaps some consternation to learn that a disease which occasionally ravages the poultry-yard is characterized by the same micro-organism. If Dr. Ribbert's observations be confirmed in every particular, our ideas concerning tuberculosis will require to be still further extended, and another possible source of infection through food will have to be admitted. For our own part we do not desire to press this suggestion too far, and will be contented with giving an account of Dr. Ribbert's research.

Tuberculosis had been unusually prevalent among poultry in Cologne and the neighborhood, so he had ample material to examine. He found the characteristic changes most marked in the intestinal tract, the liver, and the spleen. In the intestine there were beneath the serous coat nodules varying in size from a pin's head to a walnut, the smaller ones projecting beneath the mu-

eous membrane, which was puckered in a scar-like manner over the surface of the larger masses. On section these growths presented much caseation. The foci in the liver and spleen were some of them almost microscopic, others varying in size up to that of a cherry, the larger nodules being caseous in the centre. Occasionally similar nodules occurred scattered through the lungs and kidneys. All these tubercles were the seat of bacilli in great numbers, generally massed together in groups, and so abundant that in the stained sections their presence could be detected with the unaided eye. Their disposition in the nodules was peculiar. Thus in the very small hepatic nodules the bacilli were collected in the centre, the periphery being composed of inflammatory tissue. The nodules next in size presented an area in the centre partly caseous and wholly free from bacilli, which were grouped in a zone outside this. In the largest tubercles it was possible to distinguish four zones—viz., a central caseous mass, a zone of tubercular cells free from bacilli, then the bacilliferous zone, and lastly the outer zone of inflammatory tissue. It would appear as if with the growth of the nodule the bacilliferous zone continued to extend its area, and that caseation occurred, not from the direct action of the bacilli, but from the shutting off of the blood supply.

Perhaps the most interesting fact that comes out of Dr. Ribbert's work consists in the observed relation of the bacilli to the bloodvessels, particularly of the lungs, where the indurated vascularized areas surrounding caseating tubercle yielded on examination the following facts. The parallel bundles of connective tissue forming the walls of the veins were seen to be thickly invaded by the bacillus, which occurred in irregularly shaped masses, in places encroaching upon the lining membrane of the vessel, the bulging of which produced the appearance of minute tubercles, and rendered thrombosis probable. The bacilli were specially massed within the mesh-like spaces of the connective tissue forming the vessel wall. Caseation was not to be found in these structures, and the arterial walls were similarly invaded by the bacillus. It is suggested that, if the same invasion of the bloodvessels occur in the human subject, we may not have to go far to seek for an explanation of that rather inexplicable occurrence in the history of pulmonary phthisis—viz., early hæmoptysis. The vessel wall, weakened by the invasion of the micro-organism, yields before the blood-stream and gives rise to the hæmorrhage, and the discovery by Hiller of bacilli in the sputa of cases of this initial hæmoptysis seems to support the inference, which, however, should not as yet be allowed to go beyond the region of hypothesis. More plausible is the other inference which Dr. Ribbert deduces from this involvement of the veins—viz., the facility with which a general tubercular infection may arise secondarily. He is careful to point out

that there is no question here of any special form of new growth in the vessel wall; but the essential feature is the presence of bacilli in situations admirably calculated to ensure their entrance into the circulation.

A few remarks upon the character of the tuberculosis of fowls conclude his suggestive paper. The large size and advanced character of the intestinal nodules point to the alimentary canal as the primary seat of the disease, the liver and other organs being secondarily infected. It is easy to infer from this that an epidemic of tuberculosis in the poultry-yard may arise through feeding, the excreta of the fowl affording the virus. But this hypothesis has not received direct confirmation. Dr. Ribbert has not found bacilli in the excreta examined, nor was he able to induce tuberculosis in two fowls with whose food excreta from tuberculous fowls were mixed. On the other hand, he succeeded in inoculating fowls with tubercle by the introduction into the abdominal cavity of portions of the intestinal nodules. The inoculated tubercle, it may be remarked, did not occur in the intestine, but only in the spleen and liver, nor did it present many bacilli. Inconclusive as this part of the research appears to be, it opens up a new field of research, which we trust pathologists will not be slow in following up. It shows further, how much may be gained from comparative pathology upon this most interesting subject of modern research.

"MESSAGE."

THE word *Massage* has been used to designate a mode of treatment applicable to a class of cases which are by no means uncommon, and many of which have baffled the skill of the neurologist and the ingenuity of the gynæcologist. It is an unfortunate use of a term, inasmuch as it indicates only a part, for the word means rubbing or shampooing simply, and that, although a necessary, yet by no means the most essential, part of the treatment. The cases to which the method called *massage* is applicable have not been defined with sufficient accuracy; and partly owing to this fact and partly to the object of the treatment being misconceived, and to the obscure nature of the cases in which it is useful, the method has already been abused and misapplied. We have on a previous occasion called attention to some forms of abuse of it, and to prevent these as well as other forms, a knowledge of what is to be gained and what can be done by it is necessary, and this can only be acquired by the publication of all cases, unsuccessful as well as successful, in which the practice has been resorted to. The practice consists of several procedures, each of which has been long known to and employed by physicians, but not in the combined and carefully systematized manner recommended and practiced by Dr. Weir Mitchell. These are isolation of the

patient from friends and relatives, and placing her under the care of a skilled nurse; massage, shampooing, rubbing, and electricity, or passive exercise; and feeding. The practice, when resorted to in suitable cases, is thoroughly scientific, and consists simply in removing the cause of the disordered condition and restoring the strength.

The disorders for which the method is suited are, in their inception, of a very feeble character, and would probably fall stillborn were it not for the assiduous care and attention bestowed upon them by friends and relatives. The supply of the latter is, however, so abundant, that the puny infants grow to be veritable giants—giants, however, which perish like the prophet's gourd, once their source of nourishment is cut off. The cases cured by the practice appear to be of the following character; their starting-point seems to be some mental shock or trouble, overtaking of strength, or in some cases perhaps some trifling uterine disorder; sympathy, indulgence, moral mismanagement, encouragement to invalid habits from friends now come into play. The disorder will now retain its vigor without much variation, sustained by the vigilant care of friends. Soon, however, it becomes developed by the aid of the doctor—too often a neurologist or gynecologist. In proportion to the number and variety of doctors consulted will the disorder find new spheres of activity; it may assume a uterine, spinal, cerebral, laryngeal, or other character, according to the element ruling at the time; unfortunately it is too often uterine.

Dr. Playfair has published ten cases in which cures were brought about by the method we speak of. These cases had their origin in the ways we have stated. Indeed, Dr. Playfair clearly and unmistakably points out the part played by friends and by active local uterine treatment in these cases. Of the last he says: "I am not sure that I should not, in common honesty, make the humiliating confession that in many instances over-much and injudicious treatment, in my opinion at least, intensified and kept up the now dominating neurasthenic disorder, as in a case under my care as I write, in which the patient may fairly be said to be suffering from pessary on the brain, so incessantly is she thinking of one or other of the seventy-nine different instruments which she has had inserted during the last few years in America and in this country." We do not know which to admire most—the imagination which called into existence the conditions requiring the use of seventy-nine different pessaries, or the ingenuity which devised them.

How many women, fit subjects for the method of treatment included under the term "massage," go about laboring under some supposed affection of the uterus or spine, a burden to themselves and to their friends, cannot be estimated. The number, however, is by no means small. That there is no organic disease present in

the uterus or elsewhere, and that these women are invalids made by their surroundings, is proved by the fact that their symptoms disappear after a few days of separation and isolation from their friends, and that the only indication then is to restore their strength, which is done by passive exercise, rest, and feeding. In one only of Dr. Playfair's cases was recourse had to local uterine treatment. This was a case in which the uterus assumed a position of retroflexion, and, although this condition did not appear to have much to do with the symptoms, a stem pessary was introduced, fortunately without preventing a favorable issue. The treatment does not appear suitable for cases of organic disease, but rather for women who have acquired invalid habits, and for a large number of those who are always thinking of their displaced and ulcerated uteri, and of the ingenious instruments inserted and the varied applications made to cure them.

PHYSIOLOGY AND THE EXPLANATION OF CONSCIOUSNESS.

THE *Princeton Review* for July contains a paper by Professor William B. Scott, of Princeton College, on Recent Researches in Cerebral Physiology. Mr. Scott is one of the clearest headed biologists of his country, and it is of much interest to notice the impression produced on his mind by the arguments in support of the most recent doctrines in cerebral physiology. The paper is not the less interesting for being intended for comparatively popular uses. The chief doctrine, of course, in which Mr. Scott seems interested is that of the localization of function—a kind of modern phrenology, only with much more effort after a scientific basis than the old phrenologists cared for. After giving a *résumé* of the "centres" which have been indicated, and of the best established views as to the functions of the different parts of the cerebro-spinal system, Professor Scott comes to the "most important question of psycho-physiological inquiry—the functions of the cerebral hemispheres." After admitting with all physiologists that the cerebrum is the organ most indispensable for the operations of conscious intellect, he proceeds to discuss the question, "Can we find any reason to believe that the functions of the cerebrum are localized in its cortex? After reviewing the evidences for the theory of localization, those from experiments on animals and those from pathological observations on man, with much clearness, he comes to the conclusion that the mental functions cannot be localized. He lauds highly the work of Wundt, as the most important of recent contributions to Physiological psychology (*Grundzüge der Physiologischen Psychologie*, 2te Aufl., Leipzig, 1880). He thinks the best statement of our present knowledge of the complex question of localization will be found in the following propositions of Wundt:—

"1. The Connection of Elements: Every nerve-element is connected with others, and only then is it capable of physiological functions. 2. Indifference of Function: No element performs specific functions, but the form of its function depends upon its connections and relations. 3. Representative Functions: Elements whose function is inhibited or destroyed may be represented by other elements, so far as the latter stand in the necessary connections. 4. Localization of Function: Every definite function has, under given conditions of conduction, a definite place in the central organ. 5. The Principle of Practice: Every element becomes the better adapted to a definite function the more frequently it is caused to perform it."

We see, says Mr. Scott, that the cerebrum is the most essential part of the brain for mental action, and that only through it can the impulses from the sense-organs rise into consciousness, or the will affect the body. Further than this, there is very strong evidence that it is indispensable to memory. To the great question which so holds us all, and which is dealt with reverently by Professor Scott, "Has anything in our investigation given us a clue to the origin and meaning of consciousness?" he answers, "It must be admitted that nothing has done so. Consciousness is an ultimate fact beyond which we cannot go, and all attempts to explain the transition from the unconscious to consciousness are merely clever tricks to evade the real question. The materialistic hypothesis regards the soul as a function of organized matter, the result of vibrating molecules, in the same sense that heat is a product of such vibrations. But this is entirely untenable. . . . Our immediate knowledge is that of consciousness; consciousness is the fact, matter the inference."

Reviews and Notices of Books.

Localization of Cerebral and Spinal Diseases. By J. M. CHARCOT, Physician to La Salpêtrière. Translated and Edited by W. B. HADDEN, M.D. London: The New Sydenham Society. 1883.

THERE can be no doubt that the New Sydenham Society has acted wisely in selecting for publication the translation of another work by the renowned Charcot. The present volume does credit to all concerned. We congratulate Dr. Hadden upon the successful accomplishment of his task. He has presented the English-reading portion of the medical public with a readable interpretation of the lectures of the able French physician. In a preface to the lectures Dr. Hadden has brought together some portions of neuro-physiology not contained in the body of the work. We may notice in this regard a summary of the experiments performed on monkeys by Ferrier and Gerald Yeo on the visual centres in the hemispheres, with an abstract of Ferrier's inferences on cerebral amblyopia and hemiopia; an account of a new tract of spinal degeneration in the anterior part of the lateral column observed by Gowers and in another instance by Dr. Hadden; a condensed and clear statement of the recent researches into the nature of the so-called tendon reflexes by Gowers, Tschirjew, Waller, and Horrocks. This informa-

tion is valuable, and, as it is contained in a prelude by itself, unobjectionable. It is questionable, however, whether many readers would not have preferred to study Charcot without any admixture from without, and for these individuals the introduction of the views of other observers not quoted by Charcot on some debated point in neurology may appear impertinent. The translator mentions that the French edition was edited and partly annotated by MM. Bourneville and Brissaud.

We cannot praise these clinical and anatomical lectures too highly. As Charcot himself says, they constitute an introduction only to the clinical history of cerebral and spinal disease as met with in man. But such an introduction!

The first part of the work treats of the localization of cerebral disease, and sets to work in a thorough fashion by describing the broad anatomy and histology of the cerebrum. Perhaps the principal fact in the minute anatomy is the general distinction of the cerebral cortex into anterior and posterior, the former containing the large motor cells which are absent in the latter. Charcot insists on the necessity for good clinical observations and careful autopsies of cases of disease of the central nervous system. Having drawn attention to the frequency of vascular lesions in cerebral pathology, an elaborate description of what is known concerning the arterial circulation of the cerebrum follows, and forms the main subject of the next five lectures. Cerebral and hysterical hemianæsthesia are contrasted in the next lecture. Charcot has long held decided views on crossed amblyopia and lateral hemiopia. He says that lesions of the cerebral hemispheres causing hemianæsthesia give rise also to crossed amblyopia, and not to lateral hemiopia. The well-known diagram explanatory of the phenomena of lateral hemiopia and crossed amblyopia naturally finds its fittest place here. The origin of the cerebral parts of the optic nerves is dealt with next. On arriving at the twelfth lecture it is obvious that we have to do with questions of exceeding importance. The division of the central masses of the hemisphere into anterior or lenticulo-striate, and posterior or lenticulo-optic regions, is apparently of surpassing interest from an anatomical and pathological standpoint. Damage of destructive sort to the anterior region which comprises the anterior two-thirds of the internal capsule, caudate and lenticular nuclei, produces loss of motion on one side of the body without any associated hemianæsthesia, but the loss of power is less when the grey matter of this region is destroyed as compared with the pronounced and lasting palsy which accompanies the lesion of the white matter (internal capsule).

In the second part of the book, which concerns chiefly the localization of spinal disease, the predominant feature is the anatomy and physiology of the pyramidal tracts. The reader is taken through a course of most instructive lectures, and cannot fail to possess himself of the main embryological, anatomical, physiological, and pathological facts already known on the subject of the pyramidal tracts. For this knowledge we are indebted mainly to Flechsig. It is shown that during the first few weeks of extra-uterine life, according to Parrot's observations, the then indifferent, nearly uniform, grey transparent matter of the cerebral hemispheres becomes differentiated into white matter first at that part immediately beneath the fissure of Rolando. Of all the cortex of the hemisphere, that forming the "motor" region is the first to be developed. Flechsig, although differing in some details, is yet corroborated in this main fact of development. The pyramidal tract next proceeds downwards through the centrum

ovale along the posterior part of the internal capsule, behind the "knee" of this structure, which is formed by the junction of the anterior and posterior bands. In the cerebral peduncle the pyramidal tract occupies generally the middle segment of the lower layer of the crus, and may be seen as an opaque rhomboidal area, when the internal and external segments yet exist as clear spaces, due to the non-development of the medullary sheaths. Owing to the intermingling which takes place, we know but little of the precise arrangement of the fibres under consideration in the pons Varolii. In the medulla the anterior pyramids are the direct pyramidal tracts. The varying amount of decussation, and the situation, size, shape of the direct and crossed pyramidal tracts in the spinal cord are now amongst the more familiar facts of the anatomy of the spinal cord. The knowledge brought to light by developmental, by structural, and by pathological anatomy have conclusively demonstrated the essential contrast between the two constituent parts of a posterior column of the cord. No one can over-estimate the importance of the study of the secondary degenerations of the white fasciculi, not only in the cord but in the brain. A solution of osmic acid has proved of great value in these anatomical studies. In an appendix to the work some fresh evidence of a clinical and anatomical nature is afforded with the view to place anyotrophie lateral sclerosis on a sure autonomous basis. The objections raised by Leyden are here discussed and explained away. With all that we have said, we are afraid that we have done but scant justice to this modern masterpiece. It is but natural that those who read French should prefer the volume in its original dress. Things coming from Charcot, which sound pithily in the foreign tongue, rather lose their freshness when rendered into even readable English.

Artificial Anæsthesia and Anæsthetics. By HENRY M. LYMAN, A.M., M.D. London: Sampson Low & Co. 1882.

If we were asked to write a thesis in support of the proposition that the subject of artificial anæsthesia and anæsthetics was of sufficient importance to require a separate literature, we confess that we should not feel very intensely on the matter, and probably our arguments would be correspondingly lame. Dr. Lyman has, however, composed a work of over 300 pages, and has brought together a large amount of miscellaneous information. In the preface he says "the practiced expert will everywhere recognize the quality of Ferrin, of Snow, of Simpson, of Samson, of Anstie, of Turnbull, of Kappeler, and of Rottenstein." No doubt the treatise has been finished at the cost of a great deal of constructive energy, the materials from the various sources having been welded together in a systematic whole by the author; for this labor Dr. Lyman deserves much credit as well as for the modest way in which he speaks of his own share in the work. An opening chapter is devoted to the History of Anæsthesia, in this sundry allusions to ancient authors are made, showing that from the earliest ages of antiquity man has continually sought for the means of obtaining relief from pain. The phenomena observed in the course of the administration of an anæsthetic are carefully described, and the physiology of anæsthesia is fairly well entered into. Attention is next directed to the administration of anæsthetics, the method of producing anæsthesia, and the various forms of inhalers in use. Accidents and the treatment of these are explained; some illus-

trative cases of apparent death in which restoration was affected by many simple means are also quoted from medical journals. Another chapter gives an account of many Anæsthetic Mixtures which have been suggested with the hope of diminishing the perils of anæsthesia from the use of chloroform alone. Artificial Anæsthesia and Anæsthesia in Dentistry are the titles of the following two sections. Local Anæsthesia receives adequate consideration, as also does the important question of the Mortality of Artificial Anæsthesia. The Medico-legal Relations of Anæsthesia are of the first importance, and of a very extensive nature. Dr. Lyman mentions most of the many aspects of this subject, and illustrates them by means of reported cases. A description of all the chief Anæsthetic Substances occupies the remaining, and by far the largest, part of the book. Under the heading of Chloroform, the author has collected 393 cases of sudden death from the inhalation of this anæsthetic. Of these, the sex was recorded 370 times, 262 were males and 108 were females. Death occurred 15 times at the commencement of inhalation, 99 times before complete insensibility set in, 70 times whilst the patient was fully unconscious, and 35 times after the completion of the operation (out of a total of 219 available records). Some more tables are given, including one showing the nature of the operation for the performance of which the chloroform was administered. Under the chapter on Ethidene Dichloride, two recorded cases of death from the use of this agency are briefly sketched. The administration of amylene has been followed by death in two cases reported in the *Medical Times and Gazette*, 1857. Alcohol is fully treated of, both from a chemical and physiological standpoint. Cases of death caused by the inhalation of ether, and of nitrous oxide gas are also incorporated in the work. The question of the Production of Anæsthesia by Rapid Breathing and by Electricity occupies the brief concluding chapters.

Lectures on Orthopædic Surgery and Diseases of the Joints. Delivered at Bellevue Hospital Medical College during the Winter Session of 1874-75. By LEWIS A. SAYRE, M.D., Professor of Orthopædic Surgery in Bellevue Hospital Medical College, Consulting Surgeon to Bellevue Hospital, etc. Second Edition, revised and greatly enlarged, with 324 illustrations. London: J. & A. Churchill. 1883.

DURING Dr. Sayre's visits to this country he availed himself of the opportunities afforded him on many occasions of stating, and, as far as possible, demonstrating his views and lines of practice; and the teaching of this volume will not be novel in its main doctrines. In the treatment of talipes Dr. Sayre lays stress upon the value of joint pressure as determining the necessity for, and also the seat of, division of tendons. Immediately after tenotomy he places the deformed part in the correct position, and thus is exactly opposed to the usually received view that it is better to wait for three or four days before trying to correct the deformity at all. In the treatment of joint disease he relies almost entirely upon fixation of the part, combined with extension. These principles are illustrated in their practical application in affections of all the joints of the body, and the author's mechanical ingenuity is abundantly evidenced. The book, however, is too large. It could have been shortened very considerably without sacrifice, and thus have been made much more gener-

ally serviceable. There is great repetition, which, although quite legitimate in clinical lectures, is very tedious when the lectures have to be read. Dr. Sayre is a firm believer in the evil effects of congenital phimosis and adherent prepuce, and is disposed to attribute all kinds of muscular spasms and paralyses to these conditions. He cites several cases in which circumcision was speedily followed by relief to these conditions. And Dr. Sayre goes on to state, "The same general disturbance takes place in the female from irritation of the clitoris; to illustrate which and the results secured from clitoridectomy" he quotes cases. The first is of a child nine years old, with spasm of the muscles of the thigh and calf, "Pressure on the clitoris caused spasmodic contraction of the muscles of the lower extremity. I clipped off the end of the clitoris." A month after she was stated to be well. Another case is that of a child, eight years old, who was sickly until three, and then began to improve, but had never been able to walk. Dr. Sayre found her healthy, "but unable to extend her limbs at all." He "found the clitoris very much congested, and the slightest touch produced spasm of the whole body." Clitoridectomy was accordingly performed. The third case recorded is similar in all important points. We must protest very earnestly against this practice and teaching. Dr. Sayre appears to consider that circumcision and clitoridectomy are analogous operations. The loss of the prepuce for certain entails no evil, but to remove the clitoris is a mutilation only justifiable under the most extreme circumstances—circumstances which, from Dr. Sayre's account, did not exist in his cases.

On the Pathology of Bronchitis, Catarrhal Pneumonia, Tubercle and Allied Lesions of the Human Lung.
By D. J. HAMILTON, M.B., F.R.C.S.E., F.R.S.E.,
Professor of Pathological Anatomy (Sir Erasmus Wilson's Chair), University of Aberdeen. London: Macmillan & Co. 1883.

WE are glad to find that Professor Hamilton has thought fit to collect within this volume the very interesting and thorough series of papers which he contributed to the pages of *The Practitioner* a short time ago, and with needful additions, to have placed before the profession a work which we hope will be widely read and studied. It contains the outcome of extended original observation, and although in some respects it may seem to run counter to the tendencies of modern pathology, no one can deny the ability with which the author handles the problems arising out of this study. The chapters devoted to bronchitis and the diseases frequently associated with it fill a gap in pathological histology which has never been so adequately dealt with before. After describing in detail the normal structure and disposition of the bronchial passages, and the manner in which the epithelial lining is reproduced, he applies this knowledge to the explanation of the changes observed in acute bronchitis, laying great stress upon the presence of the basement membrane as preventing the catarrhal process from being, as some hold, in part due to proliferation of connective tissue corpuscles. The cellular products of catarrh are, he maintains, entirely derived from the layer of germinating epithelium. There are evidences of concomitant leucocytic infiltration of the inner fibrous coat of the bronchus and of the lymphatic structures, but there is no proof that these exuded leucocytes travel beyond the barrier afforded by the basement membrane. Another interesting fact is the state of congestion of the nerv-

ous ganglia at the root of the lung, suggestive of their taking part in the increased activity of the bronchial glands. Descriptions follow of the changes observed in chronic bronchitis, as occurring in an acute attack, in valvular lesion of the heart, from inhalation of foreign matters, etc., and then comes an important section upon chronic interstitial pneumonia as a complication of bronchitis; in which the author gives his adhesion to the doctrine that bronchiectasis is due to the contraction of the thickened lobular septa passing between the bronchial wall and the pleura.

It is, however, in the second half of the work that Professor Hamilton enters upon controversial ground, and the bold statement that he does not consider ordinary croupous pneumonia to be an inflammatory process at all, may sound strangely to those unacquainted with the arguments he proffers. The fact is he does not acknowledge that the vascular changes in the process of inflammation are, strictly speaking, "inflammatory;" the exudation of liquor sanguinis and the emigration of leucocytes are, he considers, purely the mechanical effects of suddenly increased blood-pressure, and the pneumonic exudations being solely composed of blood constituents is, he thinks, brought about by the sudden change in the condition of the pulmonary circulation, the primary cause of the heightening of blood-pressure being stagnation in the capillaries, due to spasm of the bronchial and pulmonary vessels from irritation of the alveolar walls. This subject is discussed at some length, but it does seem as if far too much importance was assigned to these mechanical conditions. Professor Hamilton, in pursuing his arguments to their logical conclusion, and in advocating venesection as "the one sovereign remedy" in acute pneumonia, says:—"I cannot refrain from expressing my strong conviction that in venesection we have the one means of lowering the blood-pressure and cutting short the disease. Once the undue blood-pressure has been relieved, the exudation of its solid constituents must cease, and time will thus be afforded for the circulation in the part to recover itself. The hard, wiry pulse of a person suffering from croupous pneumonia simply expresses the high tension of the blood. Remove part of the latter and relieve this tension, and you will cut short the disease." And he thinks that venesection has been discredited because it has been employed for cases of catarrhal as well as of croupous pneumonia, an assumption almost as gratuitous as the foregoing statements upon its value in the latter disease. Pathologically Professor Hamilton sees no difference between "croupous pneumonia" and "oedema" and "brown induration" of the lung, except in the rapidity with which the increase of blood-pressure takes place; and he regards "catarrhal pneumonia" to be the real inflammatory disease of the lung. The chapters on catarrhal pneumonia naturally lead to the discussion of tubercle and phthisis. The view taken by the author here is much the same as that promulgated by Virchow, but which is now on all sides giving way before the reversion to the modified doctrine of Laennec. Tubercle, according to the author, is a connective-tissue tumour, analogous to sarcoma, but evoked by infection from the absorption of caseous products. The giant-cells are only so far characteristic as indicating the reversion of the irritated connective tissue to its embryonic type. Tubercle may be disseminated embolically, but he finds no ground for the belief that it primarily precedes the inflammatory changes so often associated with it in the lung. It is impossible, and it would be unfair, to attempt to give an accurate idea of Professor Hamilton's teaching within the small space

at our disposal. We must refer to the work itself for this, and for his views on the supposed contagiousness of phthisis, to which the discovery of the bacillus has given such a stimulus. Professor Hamilton does not believe much in the constitutional nature of phthisis, but rather in a liability from internal weakness or from mal-hygienic surroundings, to catarrhal pneumonia, which on reaching the caseous stage, may become the source of the tubercular virus, capable of transmission. He does not, however, believe that the secretions, etc., contain this virus. We commend this work for careful study. The reader will find it pleasant to peruse, and profitable, too, for it bears the impress of convictions based upon careful observations. It is amply and beautifully illustrated, and the printing is unexceptionable.

Leçons Cliniques sur les Maladies Mentales et sur les Maladies Nerveuses. Par AUGUSTE VOISIN. Paris: Baillière et Fils.

THIS is a huge volume of 800 pages, which, probably with advantage to author and reader, might have been condensed into a much smaller compass; the present bulk, however, has the advantage of demonstrating more fully the author's facility in generalizing. Praise must be accorded to the systematic method in which the subjects are treated, and to the author's constant endeavor to associate cerebral pathology with mental symptoms. In places, however, the former merit degenerates into a fault, and becomes a mere hair-splitting subdivision. The theme of the work would appear to be the great therapeutic success of the author in the use of counter-irritation, morphia, and the bromides, together with his pathological success in discovering microscopic changes which correspond most accurately with the present accepted theories of brain function and the author's views of cerebral disease.

Counter-irritation by blisters or actual cautery is recommended in general paralysis with mania, whenever the cerebral temperature rises above the normal. In ordinary mania with cerebral hyperthermia, blisters should be used to the head and neck, with a sufficiently powerful injection of morphia to produce prolonged sleep. In ordinary melancholia, where there is temporary or chronic cerebral hyperthermia, the same treatment should be adopted; and so also in the case of stupor, but if the stupor be without elevation of head temperature morphia should be used. Morphia is recommended to be employed in the form of hydrochlorate as a subcutaneous injection in stupor, in simple hypochondriacal and hysterical melancholia, in mania, and in sensory hallucinations; the doses varying from 3 to 5 centigrammes per day in simple melancholia, to 9 or 10 in stupor, and from 40 to 60 in circular insanity. The initial dose in all cases should be from 1 to 3 centigrammes.

Of 106 epileptics treated by bromides, 37 were cured and 37 were so much improved that many had no longer fits, but only auras and vertigos. The dose is regulated so as to suppress the reflex irritability of the epiglottis, and varies from 50 centigrammes to 12 grammes daily. The success of this treatment is certainly astonishing. The pathological success may be estimated by the fact that in simple mania the changes under two months of diseased condition are differentiated from those above that period; in these last three stages of brain-cell degeneration are described. In the first stage, amongst other changes, the protoplasm of the cell becomes fatty and pigmented; in the second, the protoplasm commences to be

absorbed, is more granular and opaque, the axis cylinder becomes atrophied; in the third, the protoplasm has disappeared, the contour of the nucleus is that of the cell, the axis cylinder, is disconnected, and the secondary prolongations have disappeared.

A large portion of the work is devoted to showing that general paralysis may be associated with every form of melancholia—a fact already well recognized; and much space is also devoted to proving the long accepted conclusion that the enfeeblement of mental powers exists from the outset of, and is an important diagnostic symptom in, general paralysis. The perusal of this work cannot but excite the desire of many alienists to rival Dr. Voisin in his therapeutical triumphs; yet before adopting his modes of treatment, favorable as they appear, it might be wise to compare the total statistics of the Salpêtrière with those of similar French or English institutions. The difference should be so well marked as to convince the most sceptical therapist.

Student's Guide to the Examination of the Pulse and the Use of the Sphygmograph. By BYRON BRAMWELL, M.D., F.R.C.P. Edin. Second Edition. Edinburgh: MacLachlan & Stewart.—The author of this brochure has not only supplied a distinct want, but has done his work in a manner which will make it very acceptable to clinical students; for although no text-book on medicine fails to say something about the sphygmograph, the rationale of its employment is never very fully, and seldom very clearly, explained, and consequently vague ideas both as to its value and its indications are commonly current. Dr. Bramwell seems to possess the power of clear definition, and certainly is an adept at clear and systematic exposition. After a description of the instruments of Marey, Mahomed, and Dudgeon, and rules as to their application, he gives a full and careful analysis of a sphygmographic tracing, discusses the condition of diastole, and deals in turn with the frequency, rhythm, and tension of the pulse. No student who works with the sphygmograph with this book before him but will derive much serviceable knowledge. The domain of the instrument may be overrated, but there can be no doubt that it often gives very useful indications when properly applied.

The Students' Manual of Venereal Diseases. Being a concise description of those affections and of their treatment. By BERKELEY HILL, Surgeon to University College and the Lock Hospitals; and ARTHUR COOPER, late House-Surgeon to the Lock Hospital. Third Edition. London: Smith, Elder, & Co. 1883.—The title of this little book exactly expresses, not only the aim of the authors, but the result of their attempt to achieve it. It is a capital book, and one that students will find very useful while they are attending surgical out-patient practice; and practitioners will find it a thoroughly trustworthy source from which to rapidly refresh their memory on the practical points of diagnosis and treatment of venereal diseases.

On the Relation of the Chest-movements to Prognosis in Lung Disease. By ARTHUR RANSOME, M.D., M. A. Cantab., Lecturer on Public Health in the Owens College, Manchester. London: Macmillan. 1882.—In this volume Dr. Ransome has incorporated the observations which he communicated to the Medico-Chirurgical Society in 1881 with those in his work on Stethometry, and has reviewed their bearing on prognosis by the aid of his more recent experience. The mobility of the walls of the thorax and comparative measurements

of the chest at rest have at all times been considered most important in forming an opinion of the extent of any chronic lung mischief and the probable duration of the disease. It is so very difficult to come to any definite conclusion in these cases that any additional help is eagerly welcomed by the physician. Dr. Ransome's researches give us the first really scientific data on which stethometry as a practical guide can be said to rest, and, although we are inclined to think that he somewhat over-estimates its importance, we are none the less obliged to him for presenting us with a most valuable and suggestive book.

How to Examine the Chest. By SAMUEL WEST, M. D. Oxon., M.R.C.P., Physician to the City of London Hospital for Diseases of the Chest, Victoria Park; Medical Tutor and Medical Registrar at St. Bartholomew's Hospital; and Assistant Physician to the Royal Free Hospital. London: J. & A. Churchill. 1883.—This student's guide may be of use to the beginner in examining a chest, but beyond this it can be of but little service. It deals with the lungs, the heart, and the parts in the mediastinum; but it is far from exhaustive, whether we regard the topographical anatomy, the physical signs, or their explanation and significance in thoracic diseases. We can quite understand that, aided by demonstrations on patients, a course based on a work like this has been of great value to students before they have undertaken clinical work in the medical wards. The illustrations are sufficiently good, but the information, although correct enough so far as it goes, is so very elementary that it leaves but little ground for criticism.

Journal of Mental Science. July, 1883. London: J. & A. Churchill.—Dr. John Cleland writes in the current number on the seat of consciousness. No doubt the subject forms, and has ever formed, a highly interesting intellectual exercise; but if anyone chooses to maintain that the question resolves itself into one of verbal quibbling, we do not think he would have the worst of the argument. Dr. Cleland does not fall in with Ferrier's views on the matter. Dr. Bevan Lewis publishes the results of some experiments on caffeine in its relationships to animal heat and as contrasted with alcohol. He concludes that whilst both caffeine and alcohol alike increase to a great extent the normal heat formation, they differ in the very important feature that alcohol by an excessive and prolonged discharge of heat, greatly lowers the body temperature, whilst, on the other hand, caffeine tends rapidly to reinstate the normal temperature by retention. The remainder of the original articles deal almost exclusively with subjects most allied to alienism. We regret not to be able to find space for mentioning any of these more particularly.

Insanity; its Causes, Prevention, and Treatment. By W. HARRIS, M.R.C.P. Edin. London: Wyman & Sons.—This is a sketch of the subjects indicated in the title, and is intended for popular reading. The medical treatment does not seem a fit matter for popular treatment, and the causes and prevention of insanity are so faintly dealt with that it is to be feared the object intended will not be greatly advantaged. The author does not diverge from the accepted views on these matters.

Archiv für Anatomie und Physiologie. (His. Braun, und Du Bois Reymond.) Physiologische Abtheilung. Heft ii. und iii.—This part contains—1. Ernst v. Fleisch: Das Chronoautographium. 2. Ferd. Klug. Ueber den Einfluss der Kohlensäure und des Sauerstoffs auf die Function des Säugethierherzens. 3. A. Canini: Die Endi-

gungen der Nerven in der Haut des Froschlarvenschwanzes. 4. Ad. Zederbaum Nervendehnung und Nervendruck. 5. Wilhelm Fleiss: Das Piperidin als Anæstheticum und der Beziehung desselben zu seinem Homologen, Coniin. 6. S. Meltzer: Die Irradiationen des Schluck Centrum und ihre allgemeine Bedeutung. 7. Babuchin: Zwei Begründung des Satzes von der Präformaten der Elektrischen Elemente im Organ der Zitterfische.

Zeitschrift für Biologie. Von W. KUHN und C. VORR. B. xix. Heft 2.—This part contains the following articles:—(1) Ueber die nächsten Spaltungsproducte der Eiweiss Körper, by v. Kühne and Dr. R. H. Chittenden; (2) Ueber Hemialbumen im Harn, by v. Kühne; (3) Die Gase des Verdauungsschlauches der Pflanzenfresser, by Professor D. Tappeiner; (4) Versuche über die Raumsinn der Haut nach der Methode der richtigen und falschen Fälle, by Dr. W. Camerer; and (5) Einfluss des Bromkalium auf den Stoffwechsel, by Dr. B. Schulze.

Journal de l'Anatomie et de la Physiologie. Par C. ROBIN et G. POUCHET. T. xix. No. 3. Mai et Juin.—The whole of this part is occupied with a memoir by L. Huet on the Isopod Crustaceans. There are several plates giving illustrations of their internal structure.

The Hygiene of Armies in the Field. By ROBERT RAWLINSON, C.B. Read at the Parkes Museum, June, 1883. London: Wyman & Sons. 1883.—This paper, which was read at one of the evening meetings at the above museum, is more an account of the author's experience as the engineer member of the Sanitary Commission sent out to the army of the Crimea in the spring of 1855, than a sketch of the hygiene of armies in the field. It is an interesting record of sanitary work performed, and from this point of view may furnish practical hints for the arrangements which may be advantageously made for the carrying out of sanitation with an army on active service. The Appendix contains extracts from the Report by the United States Sanitary Commission of its work during the war of the Rebellion, and from Kinglake's "Invasion of the Crimea." The omission of the latter would not have affected the value of Mr. Rawlinson's paper.

Æsthetical Sanitation. By WILLIAM WHITE, F.S.A., M.S.I., F.R.I.B.A., etc. London: E. Stanford, Charing-cross.—"Be healthy, and only thus you will be beautiful," is the excellent lesson contained in this little book; but so many have gone before the author in decrying tight lacing, tight clothing, and tight shoeing, and in advocating exercise of the whole frame, that he must be sanguine if he hopes that fashion will recognize his claims to be heard. A fuller account would have been useful and interesting of Colonel Ling and his grand central institution at Stockholm for the "wonderful system by which more than five hundred muscles of the human body, together with very many thousands of nerves, are thoroughly and equally exercised and trained." In this connection few perhaps are aware of the value of cricket but those who have played an all-round game after long disuse, and have found out painfully the next day how many neglected muscles have been brought into play. Of the lessons of this book we can say nothing but good; it is only their enforcement which is wanting.

Knapsack Handbook, or Pedestrian's Guide. By WILLIAM WHITE, A.C., F.S.A., etc. Second Edition. London: Edward Stanford, Charing-cross. This pamphlet, by a member of the Alpine Club, contains in a handy form lists for the use of the ordinary knapsack tourist, showing what he should

wear and what he should carry, together with much short and sensible advice. The knapsack itself is not discussed, as it is taken for granted that an invention of the author's, called the "porte-knapsack," will be used, which remedies "all drag on the arms and all pressure on the breast or between the shoulders." But from beginning to end the pamphlet is the work of a man who has learned by experience what he wants himself, and the price is a small one to pay even for the grateful security from finding that one has "left something behind."

Health Lectures for the People. Delivered in Manchester, 1882-3. Vol. vi. Manchester: Heywood, 1883.—This is the sixth course of lectures published by the Manchester and Salford Sanitary Association. The subjects treated were those relating to "The Home and the Household in their Sanitary Aspects." We are disposed to think that some of the lectures are not well adapted for the class for whose instruction, it is to be presumed, they were chiefly intended, but others are very practical, plain, and instructive. Those by Dr. Ramsome, "On Some Dangers connected with Dwellings, and how to avoid them"; by Dr. Leech, "On Personal Care of Health"; by Mr. Reynolds, "On Thrift, its bearing on Health and Disease"; and by Dr. Simpson, "On Cookery for the Household," appear well adapted to promote the objects of the Association, and to point out to heads of families how they may most effectually care for the health of those in whom they are interested, and for whose well-being they are responsible.

The American Journal of Neurology and Psychiatry. New York: B. Westermann & Co. May, 1883.—In the current number Dr. Stephen Smith contributes some remarks on the lunacy laws of the State of New York as regards the provisions for commitment and discharge of the insane. The history of lunacy legislation in the State of New York shows a remarkable change in its policy of treating the insane, very like that of some other civilized countries. Max F. Eller directs his shafts against some of the narrow logic of the new penal code in regard to its medico-legal features. A case of mimicry of hydrophobia by other neuroses is sketched by Dr. James Kiernan. Some further notes on insane delusions are continued by Dr. Spitska. A short account of insanity associated with, or, as the author puts it, from, measles, is given by Dr. Madigan. The relation of dental operations to facial neuralgia by Dr. Brush; how to examine the insane by Dr. Spitska; the somatic etiology of crime by Henry Howard, and contributions to encephalic anatomy constitute the remainder of the original articles of this quarterly journal, which is printed in a clear type, not fatiguing to the sight.

Abstracts of some of the Medical and Surgical Cases treated at the General Hospital for Sick Children, Pendlebury, Manchester, during the year 1882. Second year of issue.—We are pleased to find that the valuable material which evidently exists at the Pendlebury Institution for Sick Children has not been simply confined to increasing the experience of those who have to do with the hospital. It has become a truism to say that it is impossible to make a post-mortem examination without learning something. But if anything substantial is to come of this recognition it can only be by careful records of the clinical and anatomical features of the cases. Notes ought to be taken in abundance, and everything that can be discriminated with certainty recorded. The "abstracts" before us have evidently been made at the cost of much time and labor. At first sight the adequate compensation

for such work does not appear. One would like to see some general conclusions drawn from this vast array of material. But no doubt these will be forthcoming when a few more annual "abstracts" have been published. By keeping up the statistics, for example, of chorea, and endeavoring to follow accurately a regular list of headings, the hospital would in a few years afford a large mass of evidence which would serve to enlighten some of the dark corners of this field of medicine.

Hospitals, Infirmarys, and Dispensaries. By F. OPPERT, M.D., M.R.C.P.L. Second Edition. London: J. & A. Churchill, 1883.—It is not surprising that this well-known work of Dr. Oppert should reach a second edition. It contains a great mass of information, and no one interested in hospital construction could afford to neglect consulting it. The work is in two parts. The first part is devoted to principles, and the second part to details. Dr. Oppert does not appear to have any very decided views of his own, but on every question of principle he gives the arguments *pro* and *con.*, and leaves the reader almost unbiased to form his own conclusions. There is a section devoted to hospital administration, in which a great many useful facts are given. The chief value of the book consists, however, in the details which are given of a very large number of hospitals, British, continental, and American, and a careful study of the seventy-four ground plans of different institutions must be of the greatest value both to sanitarians and architects. Some of the ground plans have become a little antiquated, and since they were made the buildings have undergone sundry tinkering (or improvements?) which are not in some cases represented. As an example we may instance the Westminster Hospital, in the plan of which the very important additions made a few years since are not shown. In spite of these slight shortcomings we can cordially recommend the study of Dr. Oppert's book to all who are interested in hospitals.

Die Elektro Medicin. Von Dr. R. Stintzing. "Antotypieverlag München." 1883.—This fasciculus is a reprint from the official report of the International Electrical Exhibition held at Munich last year. It treats of the various forms of electrical apparatus which are, or have been, in any way connected with the study of medicine. Galvanic elements, thermopiles, induction apparatus, constant batteries, both fixed and portable, Edelmann's absolute unit galvanometer, and his pocket galvanometer, Stöhrer's vertical galvanometer, apparatus for the employment of static electricity, and other accessory articles, receive full and careful descriptions. An appendix is added by Professor von Voit, on the employment of the electric light in the study of anatomical, microscopical, and spectroscopic specimens. The text is illustrated by one plate and twenty-four figures.

The Student's Guide to Dental Anatomy and Surgery. By HENRY SEWILL, M.R.C.S., L.D.S. Eng. Second Edition. 1883.—To any Medical practitioner who requires a succinct *résumé* of the various text-books on dental surgery this small book can be recommended, for, although it contains little if anything original, it conveys to the reader in a few words most of the facts and theories of dental anatomy and surgery. It is profusely illustrated; though some of the illustrations, notably 22 and 29, scarcely convey much additional information, and it is difficult to imagine why diagrams of syphilitic and of honeycombed teeth are entirely omitted. The chapter on dental irregularities is fairly good, and the one on caries a great improvement on that in the former edition,

as it gives most of the various explanations of other authors, and justly insists upon thorough cleansing of the teeth as the most likely means of preventing the onset of decay. The treatment of caries is clearly enough given, though perhaps some of the most recent methods of filling are not included. The remainder of the book treats of diseases of the dental pulp and their management, dental periostitis, abscess, necrosis, and other diseases of the oral cavity. Diseases of the antrum are very summarily dismissed, and in the section on neuralgia it is curious to notice that although decayed wisdom teeth are mentioned as an exciting cause of neuralgia, no reference is made to the fact that retarded eruption of these teeth (even when sound) is about the most frequent cause of neuralgic pains of the head and neck and even of the shoulder and arm. For the extraction of teeth this manual gives, with the aid of illustrations, copied from Druitt, clear instructions, but most unaccountably omits all reference, containing not even a drawing, of the so-called "hawk's-bill" pattern molar and root forceps, an almost indispensable requisite amongst modern dental surgeons. We are glad to find that this author (with few exceptions) does not recommend the administration or prescription of internal remedies by dental surgeons.

Medical Annotations.

"Ne quid nimis."

THE GROWTH OF "THE LANCET."

WITHIN one day of the present date—Oct. 6th—THE LANCET will have been in existence sixty years. The late Mr. Wakley's modest venture was first issued on October 5th, 1823. There are probably not ten practitioners in the United Kingdom who were at that time in the active practice of their profession and who can recall what was the first effect of the journal on the professional mind. THE LANCET was the original weekly journal for the advancement of medicine as a great power among the masses of the people. We may say so much, because no one now disputes the fact. There had been journalists in medicine before Mr. Wakley took up his pen. At that very time Dr. Roderick Macleod and Surgeon John Bacot, who had not long left the surgeoncy of the Grenadier Guards, were conducting a journal which, from a purely scientific point of view, was exceedingly well done, and was sometimes not badly illustrated. They, too, were the successors of other able editors, notably Dr. T. Bradley, Dr. Samuel Fothergill, and William Hutchinson. But these had all represented the profession in itself. The profession, the whole profession, and nothing but the profession, was their motto. Our founder took a different position. He took the people, the whole people, and nothing but the people, as his constituency; and while he never deserted the real and long-sighted interests of medicine, even as a compact professional body, he held by his text and preached from it until he succeeded beyond, far beyond, his own most sanguine expectations. In his preface to the first number of THE LANCET, Mr. Wakley tells to whom it was addressed. It was intended to be useful "to the medical and surgical practitioners of this city—London—whose avocations prevent their personal attendance at the hospitals:—To country practitioners, whose remoteness from the headquarters, as it were, of scientific knowledge, leaves them almost without

the means of ascertaining its progress:—To the numerous classes of students, whether here or in distant universities:—To colonial practitioners: and, finally, To every individual in these realms." The last promise—which we have italicized—was the keynote of THE LANCET, and it is by that it has become known and recognized as being above all class and clique. The undertaking was, and has always remained, arduous. In carrying it out, medicine as a literature has had to be simplified; "mystery and concealment" killed; "ignorance and mystery" made "synonymous;" "ceremonies and signs" deprived of their charms; "hieroglyphics and gilded serpents" deprived "of their power to deceive." These things were to be destroyed, and new things were to be introduced. When we note that the first article in the first LANCET was an introductory lecture to students at St. Thomas's by Sir Astley Cooper—a lecture, by the way, as fresh to-day as when it was delivered—we show, in part, the full life of a now sexagenarian work that has been conducted under an Editorship which has but once changed hands, and which at the death of the founder, twenty-two years ago, devolved as a sort of heirloom on his son, Dr. Wakley, the present Editor. The first principles of free and independent journalism have been and will be faithfully maintained. To what extent the little double sheet has gradually increased, this day's impression will indicate.

INTERNATIONAL MEDICAL CONGRESS, 1884.

PREPARATIONS for the eighth session of the International Medical Congress, to be held in Copenhagen from Aug. 10th to 16th, are being actively carried on. A local committee has been formed, as follows: President, Dr. Panum; Secretary-General, Professor Lange; Secretaries, Dr. Bloch, Dr. Salomonsen, and Surgeon-Gen. Joh. Møller, together with the presidents of the committees of the various sections—viz., Anatomy, Prof. Chievitz; Physiology, Prof. Panum; General Pathology and Pathological Anatomy, Prof. Reisz; Medicine, Dr. Trier; Surgery, Prof. Holmes; Hygiene and State Medicine, Dr. Hornemann; Military Surgery and Medicine, Director-General Salomon; Mental and Nervous Diseases, Prof. Steenberg; Obstetric Medicine and Surgery, and Gynecology, Profs. Stadfeldt and Howitz; Diseases of Children, Prof. Hirschsprung; Ophthalmology, Prof. Hanson Grut; Diseases of the Skin and Syphilis, Prof. Haslund; Diseases of the Ear and Throat, Dr. Meyer. The programme for some of the sections has already been decided upon, although at this early date the arrangements are all more or less provisional; and invitations are being issued for suggestions upon each programme, to be sent to the President of the Organizing Committee of the section before November 1st. Amongst the subjects proposed for debate in the pathological section are tuberculosis, coagulation—necrosis, pathogenic micro-organisms, chronic nephritis, etiology of malignant tumours, anæmia, etc.

HARVEY'S REMAINS.

WE were requested by the Registrar of the Royal College of Physicians to state that the remains of the illustrious Harvey, lying in the vault under Hempstead Church, in Essex, would be removed (with the sanction of Harvey's next of kin) to the Harvey Chapel, and placed therein in a sarcophagus provided by the Royal College of Physicians. The ceremony took place on Thursday, October 18th, St. Luke's day.

AN AMERICAN HOME FOR INEBRIATES.

THE annual report of the President of the Inebriates' Home, Fort Hamilton, N.Y., for the year 1882 is not unsatisfactory. Compared with our own puny and feeble experiments at home, those of Fort Hamilton are on a considerable scale. On the first day of the year there were remaining on the books 131 patients; there were admitted during the year 364, making a total of 495. During the year 4 patients died in the home, 2 were transferred to hospitals, and 1 to the lunatic asylum; 355 left during the year, 131 of whom are engaged in business and doing well; 49 unimproved; 104 have been lost sight of; and 71 were readmissions. The months in which the greatest number was in the home were April (190) and June (182). The nationality of the patients is as follows: United States, 359; Ireland, 73; England, 27; British Provinces, 10; Germany, 12; Scotland, 6; France, 3; elsewhere, 5. As to occupations, the largest number of patients was of the class of clerks. The great majority of patients (426) were males; females, 69. There is a want of accommodation for the better class of females, so that many applications have been necessarily refused. The number of patients received has been less than last year by 23, but the average time of residence has been increased from three to over four months.

BACTERIA NOT THE CAUSE OF DISEASE.

At a meeting of the Buffalo Microscopical Club Sept. 12th, Dr. Rollin Gregg read a paper in which he contended that the so-called bacteria of disease were nothing more than so many forms of fibrine. He has made some apparently rather rough-and-ready experiments by boiling blood on the one hand, and allowing it to "rot" on the other. All the forms that have ever been pictured as bacteria were to be observed in the boiled blood. "Rotted" blood showed even still more numerous shapes. In fact, every variety of shape, from a thread to a ring or globe, or any combination of such forms, may be simulated more or less exactly by fibrine in "rotting" blood. Dr. Gregg seems to think that fibrine contained most, if not all, of the formative forces of the organic world. We give these views that they may be compared with others which have from time to time appeared in *THE LANCET*. No difficulty in calling up the fallacies to which all positive opinions on this question are liable will be encountered by our readers.

ONLY NINETY-NINE YEARS OLD!

THERE is something very fine in the correction our careful contemporary, *The Times*, has to make in its report that preparations were being made for the celebration of the 100th birthday of Sir Moses Montefiore. It had to announce that Sir Moses on his next anniversary will be only ninety-nine! The difference may not seem very great to our younger readers; but it is, indeed, much. The correction reminds us of one which is reported to have been made somewhat promptly by Sir John Franklin when one of the Lords of the Admiralty ventured to suggest that he was too old for what proved his ill-fated enterprise—that, in fact, he was fifty. "Oh, no, my lord, I am only forty-nine!" was the quick rejoinder. Though not so rare a feat as some would have us believe, it undoubtedly still is a feat to accomplish at ninety-nine another year of life. But, from all accounts, Sir Moses Montefiore is as likely to achieve this feat as most people of his age, and we heartily wish him success. Physiologically such a success is gratifying, especially when, as in

Sir Moses's case, it involves the prolongation not of mere life, but of so many of the qualities which make life estimable at any age.

MICRO-PARASITES OF FISHES.

As a contribution to the stock of our knowledge of bacterial pathology we give here an abstract of some fresh investigations made by MM. Ollivier and Richet, published in *L'Union Médicale* of Sept. 29th, on the micro-organisms found in the lymph of fishes. By diligent examination these observers were able to detect microbes in the peritoneal, cerebro-spinal, and pericardial fluids, and even in the blood of the heart. There could be no doubt, according to them, that the forms observed were really bacteria, for they possessed undoubted powers of locomotion, or, as the authors put it, of *mobility of translation*. It was found that the bacilli could be cultivated either in the natural lymph or in prepared bouillon. If some lymph and blood be collected with all the necessary precautions no decomposition takes place, even after several months. However, microscopical examination always reveals the incontestable presence of microbes. The maintenance of the limpidity and the absence of putrefaction do not constitute a sufficient proof of the purity of an organic liquid from a point of view of bacteria. A bouillon made from beef, neutralized and filtered several times, then heated in a sealed flask in a stove at a temperature of 105° to 110° for fifteen hours, is and remains a clear pure fluid. Suitable quantities of this were introduced into some sterilized Pasteur's solution with all the essential precautions. At the end of a month no change had occurred. Inoculations were then made with blood or lymph, as above mentioned. Several specimens of blood and lymph had been kept in tubular pipettes. These pipettes were filled with the sterilized bouillon and then sealed at both ends, so that the cultures were rendered almost completely devoid of air. The liquid in the flasks and in the pipettes did not become turbid, even after several months. Nevertheless, at the bottom of the flask a light, small, flocculent deposit could be perceived with difficulty. But the microscope brought to light many kinds of micro-organisms, possessing motility and staining intensely with methyl violet. Multitudes of mobile forms were also to be seen in the tubular pipettes.

FISH IN HOSPITALS.

THE Committee of the Bristol Royal Infirmary have recently adopted the plan of having a fish diet in the house once a week. It is stated that this has effected a great saving in money, and has met with the hearty approbation of the patients and staff. With the exception of the London Temperance Hospital, where this plan has been adopted for some months past, we believe that the Bristol Royal Infirmary is the first to introduce this modification of its dietary. We are glad to learn that the friends of this institution are establishing a superannuation fund for its nurses. Such a scheme must command the support of all who are familiar with the way in which hospital nurses now do their work.

THE AMERICAN PUBLIC HEALTH ASSOCIATION.

THIS Association will hold its eleventh annual session at Detroit, Michigan, from November 13th to 16th, when the following subjects will be discussed:—

"1. *Malaria*—Its etiology and the methods for its prevention in localities or in persons; its Ameri-

can history; its specific particles; its origin; the conditions of its prevalence; its laws of extension, etc.

"2. *Foods*.—Their adulterations; healthy or deleterious modes of preservation and the function of legislation in regard to them. Ascertained facts as to adulterations in this country. Facts as to canned goods, condensed milk, artificial butter and cheese, prepared meats, etc.

"3. *Vital Statistics*.—Methods and results; defects apparent. How far foreign modes of tabulation are to be followed. Systems of collection and classification. Race vitality and the care of population as indicated by statistics.

"4. *The Control and Removal of all Decomposable Material from Households*.—The mechanical laws, constructions and appliances relative thereto. The construction of all inside pipes and their connections, their traps and syphonage, flushing, ventilation. How they shall be connected with outdoor receptacles and yet be free from ill effect.

"Methods and systems of physical education, drill, etc., suitable for the school-room, will also be discussed.

"Reports are expected from special committees on compulsory vaccination, the management of epidemics, and on diseases of animals."

SPLENO-PNEUMONIA.

PULMONARY congestion is a term which comprises all the stages intermediate between pneumonia and simple hyperæmia, according to M. Grancher. This physician has, like many others, had much difficulty in distinguishing, in certain cases, between pleurisy and pulmonary congestion. He thinks it necessary to admit that there exists a special pathological state of the lung, which he proposes to call spleno-pneumonia. The physical signs are insufficient, however, to distinguish this condition from œdema and other affections of the lung. M. Grancher has no post-mortem evidence to offer. Certainly states of lung are met with in the post-mortem room which might with advantage be termed of "splenic" appearance and consistence. But that is hardly a justification of the introduction of such a combination as spleno-pneumonia. The term does not explain itself, but the ease with which it is vocalized may possibly give it life.

ATTENUATION OF CHANCROUS VIRUS.

WE have already drawn attention to the hypothesis that the principle of attenuation may play an important part in the explanation of some of the remarkable changes which diseases undergo, either under the influence of intentionally administered agents, or from the action of quasi-accidental circumstances originating within or without the organism. The notion of destroying or annihilating a disease can only be entertained side by side with the belief that the chief factor of a disease is some tangible entity. Absolute extermination can only be aimed at whilst the micro-parasites exist in the environment. When once the organism is attacked we must trust to attenuation. Chemically the distinction between destruction and attenuation, however great, may be regarded as one of degree. In destruction we may say there is a passage from the organic to the inorganic; whilst in attenuation the transition may be to a body which is equally vital, organic, and complex with the original poison, but possessing different physiological properties. One of the latest practical phases which this new development of the principle of attenuation has received comes from the observations and recommenda-

tions of M. Aubert. The author concludes from his experimental and clinical researches that in the agency, heat, we possess an excellent means of attenuating the chancrous virus, and consequently of treating the simple chancre. He finds that a temperature a little above the normal body heat, of 37° to 38° C., destroys the virulence of the poison. It is necessary to combine elevation of the internal body-heat with that of local warmth, and practically to imitate what goes on in the organism affected with erysipelas when there is general fever and local heat. M. Aubert advises the employment of the hip-bath, made with water at a temperature of 40° to 42° C., and continued for several hours. Chancrous ulcers may thus have their virulence destroyed. This mode of treatment is considered to be the best for phagedænic ulceration, and for those subphimotic sores which ordinary dressings cannot touch. Similar treatment directed to specific buboes is said to convert them into simple abscesses. The value of the warm bath, hot fomentations, and the, at times, much derided poultice in the treatment of angry and virulent forms of inflammation has been long admitted. It is possible that a more scientific explanation than has hitherto been forthcoming of the *rationale* of these familiar remedies is afforded by the present notions of attenuation.

ASTIGMATIC KERATITIS.

AT a meeting of the Académie des Sciences recently held, M. Martin, of Bordeaux, read a paper, of which the following are the principal features. Cases of severe keratitis tending to recur are met with, more especially during the period of youth, which are believed to be dependent on corneal astigmatism. Generally, the affection is of both eyes; when one alone is diseased, it is always that which is the more astigmatic. When the eyes are accommodated for a long time, as in the careful examination of small objects, the repeated contractions of the ciliary muscles are thought to lead to disturbances in the circulation of the eyeball, which disorders tell most on the cornea. Astigmatic keratitis is observed during that period of life when the power of accommodation is at its best. Atropization of both eyes is the best mode of treatment. The use of cylindrical glasses is the proper means of preventing recurrence.

THE COUVREUSE, OR MECHANICAL NURSE.

AFTER two years' trial, the *couvreuse* has proved so decided a success that a brief description of this ingenious contrivance may be desirable. It was in 1878 that Dr. Tarnier, when visiting the apparatus devised by M. Odile Martin for artificially hatching and rearing chickens at the Jardin d'Acclimatation, suggested that a similar method might be applied with advantage to infants, especially in cases of premature birth. Two years elapsed, however, before any attempt was made to carry out this proposal; but in the course of the year 1880 a *couvreuse* was made, and brought to the hospital of the Maternité. This is a plain wooden case or box, measuring about 2 ft. 8 in. by 2 ft. 4 in., and 2 ft. 4 in. in height. The box has a double covering, the space between being filled with sawdust to retain the heat, and is divided into two parts. The lower half contains a reservoir, which holds about sixty litres of water, and is fed by a patent boiler that stands outside the box, and is warmed by an oil lamp; or hot water may be used without recourse to the lamp. The upper portion of the box forms a warm chamber, where a little basket or

cradle is placed, large enough to hold two infants. From an opening at the side, this cradle may be withdrawn, while the top of the box has a double glass covering, so that the children and the thermometer lying by their side can be constantly watched. If the water used in the first instance is cold, it takes a long time to attain the required temperature; but once this is done the lamp need only be relit three or four times during the course of the day. It is best to warm the apparatus while the infants are being fed or washed. The temperature within the *couvreuse* is generally maintained at 86° F., and though the contrast on withdrawing the child to be fed or washed is very great, amounting often to 30° F., colds are not so frequent as among the infants nursed in the ordinary manner. Altogether the experiment is considered so successful, that it is proposed to supply all the hospitals of France with a *couvreuse*, and there is every reason to anticipate good results from this measure. Nor is this all. A small portable *couvreuse* is now about to be tried which could be carried by hand from house to house. After this we shall probably have perambulators constructed on the same model. In conclusion, we should remark that, though no very careful experiments have been made with respect to the ventilation within the *couvreuse*, yet this is evidently sufficient. Apertures are made in the lower portion of the box, the fresh air travels over the hot-water reservoir, and is thus warmed before it reaches the child. The very great difference of temperature within the *couvreuse* ensures a constant current of air, though the child is protected by its cradle and clothes from any draught.

FORMATION OF HIPPURIC ACID IN MAN.

ACCORDING to Bunge and Schmiedeberg, the conversion of benzoic into hippuric acid, which results from the ingestion of the former substance, is carried out, in the dog at least, in the kidneys only. Salkowski has shown, however, that in the rabbit the transformation may occur not only in the kidney, but also in the liver and muscular tissue. An opportunity of studying the influence of the kidney in the above respect presents itself when that organ is the seat of disease. Jaarswell and Stockvis arrived at the general conclusion that renal lesions often have an influence on the metamorphosis of benzoic into hippuric acid; that influence is most marked when there is parenchymatous nephritis, much less manifest in cases of lardaceous degeneration, and not perceptible when interstitial nephritis is present. Kronecker's investigations led him to the opinion that interstitial nephritis may hinder to a considerable extent the conversion of benzoic into hippuric acid; he also found that the elimination of benzoic acid as such takes place in all forms of nephritis, and that the proportion of hippuric acid eliminated was more scanty as the renal disease was more pronounced. From the researches of Schmiedeberg it appears that not only can the animal organism bring about a synthesis, but also an analysis or splitting up of hippuric acid. The agent which determines this destruction is a ferment which is named "hystozyme." This ferment is present in several organs, in the renal amongst others. If, therefore, on the exhibition of benzoic acid very little or no hippuric acid is discovered in the urine, we ought to inquire whether the hystozyme is present in the organism in larger quantity or greater activity than usual, or whether the synthesis has never taken place between glycol and benzoic acid. Kronecker has been unable to draw any certain conclusions in this direction from his experiments. Though he found

that the administration of benzoate of soda in two cases of typhoid fever gave rise to the appearance of but trivial quantities of benzoic acid in the urine, the result could hardly be reconciled with the notion that the ferment was developed in excessive quantities.

BACILLI AND CHOLERA.

THERE is probably nothing which takes place in the universe which may not ultimately be resolved into two principal phases. Every process may be likened to the swing of the pendulum. In every natural action we almost certainly have to do with a to-and-fro or an up-and-down period. The rhythm may vary infinitely in respect of space and time, but the notion of a cycle probably pervades all cosmic phenomena. The force and truth of these general remarks are perhaps nowhere more patent than in the study of those natural phenomena—the changes of pathological doctrine. After the careful series of researches conducted by such able observers as Drs. Lewis and Cunningham, we were warranted in believing that cholera was independent of the presence of any microscopically demonstrable poison. In *The Times* of Aug. 14th a paragraph announces that Dr. Kartalis, of the Greek hospital, claims to have made the important discovery of living bacilli in the blood of cholera patients, the organisms being visible under the microscope. We shall await with interest the confirmation and further particulars of this discovery, which does not necessarily imply a belief in the bacterial origin of the affection.

COLD BATHING A HINDRANCE TO CURE.

WE are open to anything that looks like truth and sense wherever it appears. The *Monthly Homœopathic Review* is not an organ from which we can be accused of often quoting, but in the number for August there is a hint which we readily take from Dr. Pröll, of Nice and Gastein. It has reference to the case of a Russian child, aged seven, troubled with chronic diarrhoea, for the cure of which all treatment, homœopathic included, was unavailing. The boy looked exceedingly ill, face pale, sallow, emaciated, with dark hair and sunken eyes. The urine contained a sensible amount of albumen, and Dr. Pröll was in despair. At one of his visits he heard the child screaming, and ran to him and found him naked and being rubbed down with a sponge full of cold water. It instantly occurred to Dr. Pröll that this was keeping up the diarrhoea and the albuminuria, and he ordered its discontinuance and the use of more limited sponging with tepid water. Three days after the diarrhoea ceased. After a week the albumen was reduced to half, and after a fortnight "the Bright's disease was cured." This is very bad homœopathy, but it is good practice, and we gladly record it to Dr. Pröll's credit and for the advantage of all physicians.

TRANSFUSION OF BLOOD.

THE *Presse* of Vienna lately described an operation of the above kind successfully carried out by Professor Nothnagel in conjunction with Herr Ritter von Hacker. On account of the unsatisfactory results recently obtained in several cases by using human and lamb's blood, it was resolved to try a better method, already suggested by several physiologists. This consisted of a solution of common salt of 0.6 per cent. rendered alkaline by two drops of concentrated solution of soda. The patient treated on this occasion was a young man who was in imminent danger from weakness of the

heart, consequent upon loss of blood by reason of an abscess in the stomach. An incision was made in a vein in the upper part of the arm, and by means of a funnel-shaped receptacle about two pints and three-quarters of the fluid in question were introduced into the system of the patient, who is now expected to recover.

CARBON MONOXIDE AND PREGNANCY.

A DEBATED point in animal physiology is the question whether carbon monoxide can pass from the maternal to the foetal circulation. The influence of the subject outside the sphere of pure physiology is small but important. Accidentally or suicidally, a pregnant woman may have succumbed from the respiration of fumes from burning charcoal. Can the life of a viable foetus be saved by the timely aid of a Cæsarean operation? From his investigations on rabbits M. Hogyes has answered this question in the affirmative, since he was unable to detect the gas in the foetal circulation by means of the spectroscope. MM. Gréhant and Quinquaud, however, conclude (see *La France Médicale*, No. 16) that, in small quantities, carbon monoxide may pass over from the maternal to the foetal blood.

A MISTAKEN DIAGNOSIS.

A FEW months ago in a northern university town a medical man of some professional standing read a paper before a local society on what he described as a case of poisoning by salicylate of soda. The patient, a young man, aged twenty-nine, had for some days been suffering from pains in his joints, which he thought were rheumatic. One morning on trying to get up he complained of a pain in his side, and was compelled to return to bed. His wife sent to a neighboring druggist for half a dozen fifteen-grain salicylate of soda powders, which she had been told were good for rheumatism. The patient was given one of these powders, and in an hour and a half fell asleep. After sleeping for two hours he was roused up and had some dinner, but feeling very drowsy went back to bed and was soon asleep again. His wife tried to waken him three hours later, but failed to do so, and sent for a doctor, who came in about an hour, and found him comatose with stertorous breathing. The pupils were contracted and not sensitive to light, the face, neck, and ears were covered with perspiration, and the extremities cold and clammy. The treatment was very simple, consisting of mustard to the back of the neck, heat to the trunk and legs, and ice to the head. The patient was seen again three hours later, when the pulse was noted to be 100. At one o'clock the next morning the pulse was 130, and the breathing labored. Death occurred that afternoon at half-past two, sixteen hours and a half after the powder had been taken. A post-mortem examination was made, but seems to have thrown very little light on the subject. The five remaining powders were examined, and, as they gave a violet color with a solution of perchloride of iron, were declared "to consist wholly of salicylate of soda." It was stated, however, that salicylate of soda could not be detected in the viscera or in the blood, and the urine was not tested. In the discussion which followed the reading of the paper, doubts seem to have been expressed by several gentlemen present, one member suggesting that it was acute congestion of the lungs, whilst several thought that it was not a case of poisoning at all. The President, with a foresight which does him credit, gave it as his opinion that the powders consisted of morphia, with a small quantity of salicylate of soda as an

impurity. The matter would probably have remained for ever in doubt had not the widow brought an action against the druggist for £750 damages as compensation for the loss of her husband. The court ordered one of the powders to be sent to Dr. Stevenson Macadam, of Edinburgh, for analysis. From his report, just received, we learn that it contained 49.6 per cent. of morphia, equal to 52.63 per cent. of muriate of morphia! This, then, effectually disposes of what was supposed to be a very remarkable case of poisoning by salicylate of soda. We may mention incidentally that the case was compromised for £400, the druggist having succeeded in showing that he sold the drug just as he purchased it from an eminently respectable firm of wholesale dealers. There is no reason, as far as we know, to suspect anything but carelessness as the cause of this admixture. But it was carelessness of a very coarse character. It is to be regretted that in the public interest the whole course of the drug and its supply was not traced. Next to the lesson of the necessity for a little more hesitation in diagnosis, and a little more thoroughness in investigation, is the lesson taught by this case as to the insufficiency of legal investigations of this kind in Scotland. Such facts as obtained in this case would scarcely have eluded exposure under the jury system of England led by a medical coroner.

YELLOW FEVER.

A SERIES of investigations into the origin of this pestilential fever have just been made by Dr. Domingas Frieze, a Brazilian physician. He has discovered that the blood of the patient contains a micro-parasite, which appears as a minute point (micrococcus), and in one form or another continues in existence after the death of the patient. By experiment it was shown that the injection of a little of the tainted blood into the veins of a rabbit caused death in fifteen minutes. Although this might only seem like ordinary blood-poisoning, it was remarkable that all the blood of the dead rabbit was filled with the peculiar organisms. Moreover, a guinea-pig, kept closely upon earth taken from a yellow fever cemetery, died in five days, and the same peculiarity also appeared in its blood; and from this the experimenter argues that all such burying-places are constantly liable to distribute the disease. The most interesting part is the detection of the micro-parasite. Objections will readily occur to the minds of all in connection with the experiments mentioned above. The conclusion that the body dead of the fever should be burnt is only natural if the parasite be the cause of the disease.

YELLOW FEVER appears to be prevalent at Panama. The records, however, are defective, owing, it is said, to the managers of the canal being apprehensive that injurious reports may affect unfavorably their ability to procure laborers on the works.

A WRITER in the *Boston Medical and Surgical Journal* records a case of rheumatism in the horse in which salicylate of soda administered in drachm doses every two hours was of the greatest service. Most marked improvement followed treatment for twenty-four hours, and in ten days the animal was as well as ever.

DR. WILLIAM S. JANNEY has been unanimously elected Professor of Practical Anatomy and Clinical Surgery in the Medico-Chirurgical College of Philadelphia. Dr. Janney is the present coroner of the city of Philadelphia, and is well known to the profession as an anatomist and surgeon of extended experience.

Correspondence.

"Audi alteram partem."

ON MILK DIET AND THE USE OF ANTI-PYRETICS IN ENTERIC FEVER.¹

[Letter to Professor Gairdner, by J. W. Allan, M.B., Superintendent and Physician to the City of Glasgow Fever Hospital, Belvidere.]

DEAR PROFESSOR GAIRDNER—In reply to your note regarding the diet of enteric fever cases, I can only say that as yet I know of nothing which can take the place of milk. You taught us that milk was the food for fever patients, and my clinical experience has not shaken my faith in your teaching, but, on the contrary, has confirmed it. No doubt objections are urged against the use of milk in enteric fever, but I think that these objections either disappear or are reduced to very small bulk when closely investigated. As you ask for a short note, I shall be as brief as possible in discussing the subject.

Patients often object to milk. They say that it gives them "a bad taste in the mouth," that it makes the tongue and throat thick and glutty, and that it causes sickness. But we know that the "bad taste in the mouth" and the glutty state of the throat are due, not to the milk, but to the patient's condition. As to the sickness and vomiting, these may be due either to the irritable condition of the fever patient's stomach, or to the fact that pure—i.e., undiluted—milk or too much milk has been taken. If a person suffering from fever is allowed to slake his thirst with undiluted sweet milk, it is easy to understand that the overtasked stomach will soon reject its contents. It is clear that when the patient is thirsty the milk must be diluted with water, and this dilution must be in proportion to the patient's thirst. I do not think that any relative proportion can be fixed for the milk and water, nor that the amount of actual milk can be reduced to a hard and fast allowance. On these points, as in stimulation, "each case must stand on its own merits." But I should incline to put the maximum daily allowance of pure milk at, say, four pints. Of course it is clear that when a patient drinks little milk copious dilution is out of the question. When the patient's stomach is very irritable and vomiting persists, we add lime-water to the milk in varying proportion, from a tablespoonful to the mug up to "half-and-half." The results as a rule are satisfactory, and I think that this safe and simple remedy should never be forgotten. Soda-water in the milk is also good; ice is often very useful; but I have great faith in the value of lime-water in these cases. I have said that the patients often grumble against the milk. What would they like? Cold water, lemonade, etc. But we know that there is not much nourishment in water or lemonade. Certainly they could not take the place of milk. Occasional moderate drinks of cold, and more especially iced water, are very grateful, and I believe beneficial, to the enteric fever patient. Lemonade I fight shy of because some patients will not taste milk if they are indulged in lemonade, and I think the latter is apt to cause flatulence. It has been urged that milk in undigested curdy lumps and masses passes from the stomach into the bowels, and there gives rise to pain, flatulence, and severe diarrhoea. I do not doubt that this sometimes occurs, and I will even admit that in some cases such an occurrence may occasionally

be unavoidable. But I am convinced that, as a rule, this misfortune is due to the same causes and is amenable to the same remedies as the vomiting to which reference has already been made. In a word, I think that when this happens the patient has been drinking rich or undiluted milk, or that he has loaded his stomach with too much at a time. The remedy is to dilute the milk, add lime-water freely, and to drink in moderate draughts.

I think that you, Sir, used to draw our attention to the familiar but instructive case of the teething child. The infant being out of sorts and irritable, the fond mother gives the unhappy little being the breast whenever it cries, the nipple being regarded as a panacea. We all know the results: vomiting, gripes, diarrhoea. It is simply an instance of a stomach overloaded with milk which cannot be digested, and is therefore got rid of by vomiting and purging. The case seems exactly parallel to that of the enteric fever patient who is gorged with pure milk.

We see that the patient frequently prefers water or lemonade to milk, but now let us ask what the physician would propose to substitute for milk. The reply seems to be "animal soups," let us say beef-tea and chicken soup. But neither chicken soup nor beef-tea is an equivalent for milk from a nutritive point of view, and patients in the acute stage of enteric fever do not generally relish these things; even very good beef-tea disgusts them; and we find that these soups have a very marked tendency to originate diarrhoea or to aggravate it if present. I am quite prepared to acknowledge that beef-tea and chicken soup may be admissible in enteric fever when cautiously administered along with milk: nay, more—I think they are useful in cases where constipation is a source of annoyance; but I am certain that they cannot take the place of milk, and in many cases their use is clearly contraindicated for the reason already mentioned—viz., their tendency to cause diarrhoea. No one would seriously propose arrowroot or cornflour as substitutes for milk, although sometimes they may be added to beef-tea with advantage. We come back to this, then, I think, that milk is the staple article of diet in the acute stage of fevers, more especially enteric fever. In typhus and scarlet fever considerable latitude in diet may be permitted in some cases, even in the acute stage, such things as porridge and milk and tea and toast being frequently taken with relish, and apparently well borne and digested.

I may mention here, as an experience of this hospital, that if by accident our milk "turns," or we are disappointed in our supply, we are at our wits' end, for there is nothing that can take the place of the precious milk. And milk is not only a safe and suitable food for enteric cases; when diluted and iced, it is also a grateful drink, and it forms as well a valuable vehicle for stimulants, and even medicines. Where there is great prostration and exhaustion, egg-flip (composed of eggs, brandy, and milk) is excellent. Our experience clearly points to the fact that nothing but milk diet and fluids should be allowed till the evening temperature is steadily normal. If this rule is broken by way of concession to the patient's cravings for food "stronger" than milk, almost inevitably the penalty has to be paid. The temperature rises again; the patient is not so well; it may be that a "relapse" ensues. Chicken soup and arrowroot, or cornflour and milk, are generally the first concessions in diet. Our nurses remark that common bread is very apt to induce a rise of temperature in the early stage of convalescence. The probability is that the patient "bolts" the bread without thorough mastication, and there-

¹ Published with Dr. Gairdner's permission.

fore it should not be given dry at first, but rather in the form of panada.

As regards the employment of antipyretics in enteric fever, I can only say that I have not much faith in the administration of such drugs as quinine and salicin. Of course, I do not mean to deny the interesting fact that these agents lower the patient's temperature, but I have not been able to satisfy myself that they really better the patient's condition. If the temperature went very high I might employ large doses of quinine or salicin, but in the great majority of cases I should certainly abstain from their use. I have no proof that they really improve the patient's state or shorten the course of the disease. Of the use of the cold bath in enteric fever, I have no personal experience, and therefore I shall say nothing concerning it. The warm pack has little or no effect in reducing the temperature, but I have found it to be a most valuable means of treatment in restless, irritable, delirious cases. The soothing effect is very striking. Sponging is a safe and simple method of relieving a feverish patient. Vinegar and tepid water may be employed. As a rule the process is enjoyed by the patient, who is cooled, soothed, and refreshed by the grateful application.

I have tried to keep to the two points indicated in your note—viz., milk diet and antipyretics in enteric fever. There is nothing new in my experience; I have made no discoveries; I am still guided by the old landmarks. In conclusion, I shall say that there may be a more suitable diet than milk for fever patients, but it has not been discovered as yet.

Your affectionate old pupil.

JAMES W. ALLAN.

City of Glasgow Fever Hospital, Belvidere, Jan. 20th, 1882.

ON THE NECESSITY OF EXPOSURE OF SOFT CHANCRES WITH REGARD TO TREATMENT.

To the Editor of THE LANCET.

SIR—Too often one sees in hospital practice a condition of sloughing phagedæna which has extended around the corona and involved the glands, with a history of its having begun as a small sore. These cases are much worse where the prepuce is long, for the pent-up putrescent discharge finds no escape owing to the œdema, and the mischief commencing as a chancre involves the opposed surfaces of mucous membrane, and sooner or later the whole glans and foreskin are one sloughing offensive mass. Besides several others which have lately been admitted, there are now under treatment here three patients the subject of extensive sores of the penis.

In the first case phimosis had existed one week; there was a fetid discharge from the orifice; no sore felt on external manipulation, but a large ragged ulcerating surface, covered by a detached slough, was exposed by an incision through the prepuce; this ulceration surrounded the neck of the glans, and had invaded the tissues nearly down to the urethra. Again, in the second case we had to deal with a sore of the corona, and another at the urethral orifice; both these had the appearance of extending, and were completely hidden by a long œdematous foreskin.

The third case was characterized by sloughing phagedæna of the penis and fore part of the scrotum, with brawniness of the perineum and pubic region. Here multiple incisions were made, tension relieved, and the sloughs removed. The surface of the penis was black and gangrenous. The above patients are up and about the ward, and shortly will take their discharge.

The plan advocated is simply to slit up the prepuce upon a director with a curved sharp bistoury, without anæsthetic. The fear sometimes entertained that the recently cut surface may become specifically affected is practically groundless, so long as it is kept clean. The form of local application is second in importance to the prevention of coaptation of the opposed mucous surfaces.

As gonorrhœa is so frequently concomitant with chancre, it is obvious that this can only be diagnosed and treated with certainty by completely exposing the orifice of the urethra. The formation of bubo with its long-lasting sinus is obviated, the local treatment of sore greatly hastened, and the prevention of cicatricial tissue between the glands and prepuce prevented by the above operation, and I think the results are superior to circumcision, because the incision is not so long in healing, and the organ rendered by no means more unshapely than by the complete removal of the foreskin.

The object of these brief remarks is not to claim any novelty or originality in the treatment, but to enforce the importance of exposing the mischief early, so that it can be treated locally with the best possible result.

I am, Sir, yours obediently,

PERCY POTTER, F.R.C.S.

Kensington Infirmary, July, 1883.

"FITS" OF AN UNUSUAL KIND.

To the Editor of THE LANCET.

SIR—An account of the following case, which is under my charge in the European Station Hospital here, will, I think, be interesting to your readers.

J. C—, aged twenty-eight, gunner R.A., was admitted to hospital on Feb. 28th, suffering from ague, which was cured in a few days by the administration of sulphate of quinine. As he was suffering from general debility, anorexia, and anæmia, and was unable to perform his duties, he remained in hospital till March 14th. On that day he told me that for three months he had been subject to fits, which he thus described: first there was a rushing sound or sensation in the back of his head, then he lost all power of motion, his eyes closed, and he was unable to speak, and although he could hear people talking he could not make out what they said. These fits always occurred when he was in bed lying on his left side or back, and he was sometimes able to put them off by jumping up or turning when he felt them coming, but they usually came when he was asleep. When found in a fit the body is covered with cold perspiration, and when revived he comes to with a great sigh and feels weak for some time. I have not been able to see one of these seizures myself, but have questioned some of the patients in the same ward and also the apothecary in charge of him. They state that he lies on his back moaning, with his eyes shut (apothecary reports pupils contracted), and without any working of the limbs or frothing at the mouth. If an arm or leg is raised, it falls again as if the muscles were all relaxed; the pulse is slow but regular, and the sphincters are not relaxed. His family history is as follows: Father dead, cause unknown; mother dead, "fever(?)"; grandfather dead, paralysis; one brother and three sisters alive and healthy. Patient had syphilis in 1879, and dates his illness from last year, when he was 128 days in hospital with abscess somewhere about the ankle-joint, which is supposed to have been due to syphilitic deposit. He has not had an attack since March 25th; has not slept in bed since the 23rd of that month, but sits in an arm-chair all night and generally sleeps well in

that position. The seizure on the 25th was not nearly so severe as usual. The treatment was quinine, iron, and strychnine; arsenic and quinine; blisters to the nape of the neck; light nourishing diet and a little wine or brandy. At one time the heart's action was a little irregular, but three minims of tincture of digitalis three times a day soon made it all right. Within the last week he has complained of nervous shivering at night, keeping him awake. His bowels have been quite regular throughout, and the urine normal.

If any of your readers can throw any light on this case, I shall be glad to hear from them through your columns. The case does not seem to be epileptic, nor, what is more rare, cataleptic. If syphilitic, it is very extraordinary, and such a case has not been heard of before by yours faithfully,
M. B., India.

Dinapore, Bengal.

SOUND CLARET.

To the Editor of THE LANCET.

SIR—No stimulant is so frequently ordered for patients by doctors as claret, and no wine is so excellent when free from acidity; it therefore becomes, both for sanitary and luxurious reasons, of the greatest importance to prevent the fermentation which produces vinegar. How often does it happen that in drinking, day by day, a dozen of claret, at say 1½ ls. per dozen, one or two bottles are found deliciously free from acidity and in just as prime condition as when the wine was first made? Why is this? Obviously because (every precaution notwithstanding) air has permeated through the corks of the unsound claret. One can buy claret quite sour at about 18s. a dozen, for which, if sound, scores of people would give treble the amount. I now offer as a suggestion that bottles should be manufactured with such a neck as could easily be broken when they were required to be emptied, and which, at the time of filling, could be rendered hermetically air-tight by the glass being fused, as is done to a thermometer.

I am, Sir, yours obediently,
M.D.
Brighton, Sept. 29th, 1883.

CASE OF BEAD-SWALLOWING.

To the Editor of THE LANCET.

SIR—I send you the following case, thinking it may be of interest as showing both what a child may go through and what may go through a child without harm resulting.

On the evening of the 15th inst. I received an urgent message to go and see Mrs. S—'s child, who had "got something in its throat," and they were afraid it was choking. Putting a probang in my pocket, I quickly reached the house, and was astonished to find the child, a little thing eighteen months old, sitting in its mother's arms, and, except for a slight paleness, looking quite well. The mother's tale was to the effect that the child was sitting playing on the floor while she was washing, when suddenly it began to vomit. She immediately took it up, thinking it must have picked up something and swallowed it, as the vomiting came on so suddenly. Nothing but its food came up. None of the vomit was saved, so I had no chance of examining it. There was no difficulty of breathing or swallowing, and no pain on pressure over the stomach. I was inclined to think the mother mistaken as to the cause of the vomiting, but, as a precautionary measure, told her to feed it on dry food—biscuits and the like, and give it as little fluid as possible. The vomiting ceased, and no further symptoms declared them-

selves. On the following Monday, however, the child passed a somewhat hard motion, and with it a number of glass beads, well wrapped up in the motion. Again the bowels were moved and a like result; this time a bone button was passed as well. Very little pain was caused by the passage of these matters. The beads, when counted, numbered seventy. They are hexagonal-sided, measuring each about three-tenths to one-fourth of an inch in length, and about two-tenths of an inch in diameter—not large certainly, but numerous. The edges of the beads were sharp and ragged. The button is three-quarters of an inch in diameter, and is an ordinary horn coat button. The child, I am glad to say, has not experienced as yet (it is now a week ago) any bad effects from its curious, if ill-chosen, meal. When the child's age is taken into consideration (eighteen months), I think we may congratulate it on its safe deliverance from such indigestible materials as glass beads and coat-buttons.

I am, Sir, your obedient servant,
ARTHUR H. BOISSIER.

Pocklington, Yorks, June 22nd, 1883.

LENGTH OF INCISIONS IN OVARIOTOMY.

To the Editor of THE LANCET.

SIR—I read Mr. Sydney Jones's paper on "Five Consecutive Successful Cases of Ovariectomy," with, I must confess, a certain amount of astonishment. I refer to the length of his incisions. The length of the incisions in the five cases average 5.1-5 in.; of course, such a length of incision facilitates the ease with which an operation may be performed; but what about the future comfort of the patients? Now, it may be presumption in me to say so, but I think such an incision as 6 in. unnecessary in almost any case, let alone in such a case as E. J., where the solid weighed only 1 lb. 10 oz, after the eighteen pints of fluid were removed. Think of the future trouble that E. J. may suffer with her 6 in. cicatrix, compared with a patient with a 2½ in. incision. The operations being done in hospital, doubtless Mr. Sydney Jones had several on-lookers, and perhaps each of them carried away the idea that there must necessarily be a long incision in all ovarian cases, and so the long incisions are likely to be perpetuated as far as they are concerned. It has been my privilege during the last few months to have seen a very great many abdominal sections in Birmingham, both with Dr. Savage and Mr. Lawson Tait, and I here tabulate the last nine consecutive successful cases of ovariectomy I have seen under Mr. Tait. J. K., 2 in.; E. S., 1½ in.; E. L., 1½ in. (bad pelvic adhesion); E. W., 2½ in.; M. F., 3½ in. (both ovaries removed, bad adhesions); S. R., 2 in.; R. E., 1½ in. (dermoid); M. H., 1½ in.; J. P., 1½ in.; the total being 17½ in.; not quite 2 in. per case. These are not picked cases, but the last ovarian cases (all successful) I have seen. I may say that in small myoma cases Mr. Tait's incisions rarely or ever exceed 1½ in. Of course, it is more difficult to get hold of the tumour and break down adhesions with such a small opening, and here is the operator's skill, and the benefit to the patient is incalculable, both in rapidity of recovery from the operation and her future comfort and safety. I also note that all the cases were dressed antiseptically, and in all of them the temperature was over 100° at some period after the operation. In No. 3 it was 101.2° once, and in No. 5, 101.4°. Neither Mr. Tait nor Dr. Savage uses any antiseptic whatever, and yet they hardly, if ever, have a case where the temperature reaches 100°. If all abdominal sectionists had my opportunities of seeing abdominal surgery as car-

ried out by Mr. Tait and Dr. Savage, they would relegate Listerism in that particular branch (however useful in other surgery) to the things of the past.

I am Sir, yours obediently,

EDW. M. OWENS.

Leamington, August, 1883.

P.S.—Mr. Tait, on Saturday last, in private removed an ovarian tumour that weighed 120 lb., and his incision for this was only 3½ in.

ETHER AS A RESTORATIVE.

To the Editor of THE LANCET.

SIR—I am desirous of adding my testimony to the value of ether subcutaneously injected. I have used it for some years, and with good results, while in some cases, as in the one detailed below, with marvellous success.

In March, 1877, I was asked to meet Mr. H—, of Croydon, to see Mr. J. B—, aged about forty-five, suffering from typhoid fever in its last stage (I think the fifth week of the attack.) I found him in a state of muttering delirium, pulse scarcely to be felt, picking the bedclothes with his fingers, sinking down in the bed, etc. His tongue was black and quite filled his mouth; lips swollen and covered with black sordes, and very pinched and exhausted aspect. It was quite evident there was no possibility of giving any medicine by the mouth in his present state. I therefore suggested to Mr. H— that we should inject ether. He agreed to the proposal, so, as I had brought both syringe and ether with me, I proceeded to inject twenty drops deep into the muscular tissue of the right thigh, to be repeated every four hours. We arranged to meet for another consultation on Monday (this being Saturday) if the patient were still alive, when, meeting Mr. H— on the Monday and asking after the patient, he said, "Oh! he's all right, and setting up in bed drinking a glass of champagne." His tongue was clean, and, in fact, he was what is called "out of danger." He made a quick recovery without a drawback, except tenderness and pain in the soles of the feet, which he has had for months.

I think there can be no doubt that in this case the ether had a marvellous effect. From the recollection of this case I have determined to use ether, or perhaps some other acid, subcutaneously, should cholera come under my care.

I am, Sir, yours truly,

JOHN LACEY.

Cornhill, E. C. August, 11th, 1883.

REMOVAL OF A PIECE OF STEEL EMBEDDED IN THE LOIN FOR TWENTY YEARS.

To the Editor of THE LANCET.

SIR—The following case I think worth bringing under your notice and that of the medical profession.

John H—, seaman on the s.s. *Lord Gough*, American liner, came to consult me on June 27th, during our voyage from Liverpool to Philadelphia. He complained of great pain and a hard swelling in the left lumbar region, which prevented him from attending to his duties. I examined the spot, and found it very much inflamed and hard, and something black protruding from the centre. I then questioned the man as to whether he had received a hurt of any kind, and he stated that about twenty years ago he was a sailor on an English ship named the *Henrietta*, and was lying in Shanghai, and alongside of them were a number of Chinese junks. He went on board one of them, and when returning to his ship was set upon by

some foreign police and stabbed by one of the same in the back with a cane-sword. He was under the doctor's care for about three weeks suffering from what he thought to be a fractured rib, but after that time he was considered cured, and did not feel any pain or inconvenience until May last. Having received this history, I proceeded to make a closer examination, and found a piece of sharp-pointed steel about 3½ in. long and 3-16th in. wide, corroded, about 1½ in. from the point, and presenting at the other end an old fracture. This had become encysted in the muscles of the back. I at once extracted it, and then applied linseed poultices to draw away the pus which had formed, and after a few days' treatment the man was perfectly well, and able to go back to his duty.

I am, Sir, yours truly,

L.R.C.S.I.

August 6th, 1883.

FACTS ABOUT TYPHOID.

To the Editor of THE LANCET.

SIR—An epidemic of typhoid, which I am pleased to say has subsided, has afforded me an opportunity of recording some few cases which, I think, may possibly be of interest to your readers. I well remember my esteemed old master, Professor Rainey, taken to task by my friend, a first-year's student, on some slight apparent discrepancy between his statements and what the text-book taught. For many months afterwards he would often turn to my friend in his ever kind but sarcastic way, and ask, "What do the books say, mister?" I almost think I might put the same query in regard to the following cases, and what would their answer be?

A. B., aged thirty, married, pregnant four months with her third child, had well-marked typhoid. Temperature 104°; pulse 120. Diarrhoea spots and deafness. Did not abort.

M. R., aged thirty-six, married, pregnant seven months with her fifth child, had well-marked typhoid, diarrhoea, spots and deafness. Temperature 104°. Labour did not come on; went full term. The husband died with typhoid at the same time the wife was lying ill.

G. B., aged seventeen, M. B., aged thirty (mother-in-law and stepson), had well-marked typhoid. After the disease had been in existence for a week, the two youngest children, C. B. and E. B., were sent away into the country, a most healthy part, leaving the father and one child, F. B., and the servant to nurse G. B. and M. B. After an absence of five weeks and three days C. B. sickened with typhoid fever, as well as A. C., a child staying in the house where C. B. and E. B. were lodging. How can we account for the appearance of typhoid in the fresh locality—viz., after the lapse of five weeks and three days? I may here state that F. B., who had been left behind to nurse G. B. and M. B., or rather assist the nurse, went over to see her younger brother, C. B. This occurred three weeks before C. B. and A. C. sickened at all. During her stay of two days she slept with C. B. and A. C. F. B. had not been sick or sorry for a single moment. Might I ask, how did C. B. and A. C. get typhoid? Did C. B. have typhoid latent in his system, and so infect A. C., or did F. B. infect both C. B. and A. C.? What would the books say about infection here?

E. S., aged twenty-two, sickened with typhoid; symptoms well marked. There was not the least doubt as to the nature of the case, as three houses in the same row had typhoid fever; in none of these were diphtheritic symptoms present. After a lapse of seven days the patient complained of

sore-throat. I may say I had examined the throat carefully during the week. The whole back of the throat was covered with a thin white film, having the most peculiar appearance, almost suggestive of a thin coating of milk, as if one could see through the thin membrane. It covered both tonsils, and extended into the uvula. The following day the membrane had become much more characteristic, and had extended over a considerable part of the hard palate. It was now yellow and much thicker, and no doubt could possibly be made in its diagnosis—typhoid complicated with diphtheria. The patient hovered between life and death for the next five days, at the end of which time the membrane had entirely disappeared, and only left the patient weak to struggle on against the typhoid fever. I cannot say whether the treatment used had anything to do with the almost magical disappearance of the membrane—viz., constant spraying the throat with lactic acid. The patient made an uninterrupted recovery when once the typhoid had reached the turning point. The temperature did not go beyond 105° at any time. The pulse once reached 140.

I am, Sir, yours truly,
MONTAGU H. C. PALMER.

July, 1883.

PUBERTY IN NEGRESSES.

To the Editor of THE LANCET.

SIR—It seems a very common opinion, generally admitted all over Europe, that puberty occurs earlier in hot climates than in those lying within the temperate zone. Müller says some are of opinion that in the hot regions of Africa the changes of puberty take place in the female sex as early as the eighth year, and during the ninth year in Persia. It is also stated that young Jewesses menstruate earlier than other females in England. I am of opinion, however, with Mr. Robertson, of Manchester, who some time ago essayed to controvert this belief, that it is no other than a vulgar error. To enable me to obtain the necessary information with respect to negroes, and my interest is great, as I am from the tropics myself, I have strained every nerve to "hunt up" the necessary statistics, which I now append. These statistics I have obtained from a register of births, the registry being important in fixing the date of the first appearance of the catamenia. The under-mentioned will, I consider, confirm the belief that menstruation does not commence earlier in negroes than in female Europeans. (*Vide* Dr. Copland's Dictionary of Practical Medicine, article Age, and also Dr. Good's Practice of Medicine, article Puberty.) Out of twenty-one cases, menstruation appeared in one aged sixteen, in three at fifteen, in three at fourteen, in three at thirteen, and in two at twelve; whereas it had not appeared in one aged fourteen, in two aged thirteen, in one aged twelve, in one aged eleven, in another aged ten, one aged nine, and in two aged eight. It is further stated that many cases of negroes from eight to eleven years of age might be instanced who have not yet had any menstrual secretion.

I am, Sir, yours obediently,
C. S. TAYLOR.

Woburn-place, Russell-square, W.C., Sept. 19th, 1883.

ANALGESIA BY THE PROPOSED NEW METHOD.

To the Editor of THE LANCET.

SIR—My pupils, not I, have proposed to employ on our species the method I have discovered of producing analgesia in monkeys, dogs, and

other animals. I am not prepared to make such a proposal; not that there is any danger in the method, nor that the degree of analgesia is insufficient, but because I have not yet succeeded in devising for clinical use an easy means of applying carbonic acid or chloroform vapor to the mucous membrane of the larynx, without allowing these substances to go into the lungs. This last point is of absolute necessity, as when these substances enter the blood, they can no longer produce, by irritation of the mucous lining of the larynx, their wonderful effects.

My experiments, some already published, others quite new, show that an irritation of the laryngeal mucous membrane (and also, but in a much slighter degree, of the lining of the upper part of the trachea) can, through the superior laryngeal nerves, or even through one of them only (but then the analgesic effect is chiefly unilateral), act on the nervous centres in such a way as to produce a more or less complete inhibition of either the power of perceiving impressions able to give rise to pain, or of the power of transmitting those impressions. Every kind of irritation (mechanical, thermic, chemical, or galvanic) of the terminal ramifications of the superior laryngeal nerves can produce that effect; but none in the same degree and with so great a persistence (in monkeys sometimes the analgesia lasts more than twenty-four hours) as the excitation due to carbonic acid or chloroform vapor, the first especially. The power of the parts I have named in producing an inhibition of the kind of sensibility relating to pain, without disturbing any other power or function of the nervous centres, is so great that sometimes a partial section of the larynx or trachea produces a temporary and almost universal, but incomplete, analgesia.

I am, Sir, yours faithfully,
C. E. BROWN-SÉQUARD.

Paris, Sept., 1883.

SULPHO-CARBOLATE OF SODA A REMEDY AGAINST BEE-STINGS.

To the Editor of THE LANCET.

SIR—The following case may prove of some interest to your readers. Mrs. T—, married, aged forty, consulted me upon Aug. 25th, having been stung by a bee upon the upper part of the forehead. I was unable to discover the exact position of the sting, the whole of the face being in such a swollen condition. I therefore prescribed a hot soda bath, a saline aperient, and lead lotion to be applied to the face. On the following morning I was hastily summoned to the patient's house. I found her suffering from great nervous excitement, at times delirious, the head and neck enormously swollen; the upper and lower extremities were cold, stiff, and also much swollen; pulse almost imperceptible; breathing labored. I returned home and, with the aid of a brother practitioner, discovered in an old medical journal that Dr. Klamann had given carbolic acid hypodermically in a similar case with success. I, however, tried fifteen grains of the sulpho-carbolate of soda in an ounce of water, every four hours, which was administered with some difficulty, with the following results. After the second dose the swelling and other symptoms rapidly diminished in intensity, she became bathed in a profuse perspiration, and, during the administration of several more doses, the patient steadily progressed towards convalescence.

I am, Sir, your obedient servant,
THOMAS EDWARDS, M.R.C.S., L.R.C.P. and L.M.
Harrold, September 4th, 1883.

News Items, Medical Facts, &c.

DR. JAMES DOWLING THRASK, of New York, died recently, aged sixty-two. Dr. Thrask was one of the founders of the American Gynecological Society, and had contributed somewhat largely to obstetrical literature.

THE death is announced, at the age of eighty-two, of Dr. John Allen, of New York, who, it will be remembered, was the first to reach the side of President Lincoln, after receiving the fatal wound from the pistol of Wilkes Booth.

WE learn that a young physician practicing in Chicago, Dr. Frank Lee Rea, died a short time since from malignant carbuncle of the lip. He was a man of very good abilities, and had greatly endeared himself to all who knew him.

AN interesting paper on the Destruction of Fish and other Aquatic Animals by Internal Parasites, read by Dr. Spencer Cobbold at the Conference at the International Fisheries Exhibition on July 12th, has been printed, in which the life history of the *Ligulæ* is traced at considerable length. Much useful practical information is being disseminated by means of this excellent series of "Conference Papers" of the Exhibition.

A SERIES of thermometric observations on patients suffering from uncomplicated fractures has been recently made by Dr. Grundler. He found that in every case but one of those examined a rise of from 2° to 4° F. above the normal, and that the degree of fever is in proportion to the size of the broken bone and to the degree of extravasation. The highest temperature observed (102.5°) was in a case of fractured femur, and the lowest (100.5°) in fracture of the forearm. The rise began on the evening of the first day, and reached its highest point on the evening of the second to the fourth day.

REMARKS ON HYDROPHOBIA.—As an interesting, lucid, and pleasant brief paper on hydrophobia, we may call the attention of our readers to some remarks by Dr. Dulles, read before the Philadelphia County Medical Society. Dr. Dulles would strongly recommend every investigator to peruse a very valuable series of articles—not referred to by a single writer on hydrophobia—on the physiology and pathology of the saliva, by Dr. Samuel Wright, which were published in *THE LANCET* during 1842 and 1844. Dr. Dulles gives a brief sketch of the history of rabies in regard to the various features of the disease. The amount of information pressed into eight pages is truly remarkable.

DR. JACOB S. MOSHER, a distinguished physician of Albany, N.Y., died suddenly on Aug. 13th. He graduated at the Albany Medical College in 1863, and early in the following year entered the corps of volunteer surgeons for New York troops, and was attached to the Army of the Potomac as it lay before Petersburg. He was subsequently made Assistant State Medical Director of the State of New York, and went on duty at Washington. From 1869 to 1873 he was Surgeon-General on the staff of Governor Hoffman, and was afterwards Deputy Health Officer of the port of New York. Since vacating that appointment he had practiced in Albany with considerable success, gaining the respect and esteem of all with whom he was brought into contact.

WE have received the first three numbers of the new weekly journal of the American Medical Association. It consists of thirty-two pages of scien-

tific matter, and is evidently being conducted with energy and skill. In the first number we find the minutes of the recent annual meeting held at Cleveland, Ohio, and the addresses then delivered and papers read are being published in the succeeding numbers. The journal promises to be of much greater value than the annual volume of the "Proceedings," which it supersedes.

[The *Journal of the American Medical Association* is published at 65 Randolph Street, Chicago, Ill., by the American Medical Association, and is edited by N. S. Davis, M.D., LL.D. Yearly Subscription \$5.00.]

COCOANUT AS FOOD.—Some extraordinary stories are told of the value of cocoanut as an efficient food. The following instance is given by the *Fiji Times* :—

"A vessel that once left San Francisco with 400 passengers for Sydney had, in consequence of running short of stores, to put in at Samsa, where a large quantity of cocoanuts were obtained. During the remainder of the passage very heavy weather was encountered, in which the vessel became waterlogged, and only reached Sydney after a perilous journey of eighty days, during which time all the provisions ran short, and men, women, and children were fed only upon cocoanuts, being at last reduced to one per diem for each adult. Notwithstanding the diet, not a life was lost, not a single case of sickness occurred, and all the passengers landed in a healthy and well-nourished condition."

IMPORTANT DECISION OF THE SUPREME COURT, ON IMITATIONS.—In July, 1882, the Supreme Court of Rhode Island, by Final Decree, enjoined William H. Hughes, Theodore S. Hughes, and the Hughesdale Manufacturing Company from offering for sale "Acid Phosphate," so called, in any package which shall be a substantial or colorable imitation of Horsford's Acid Phosphate.

Sept. 24th, 1883, the Court decided that William H. Hughes and Theodore S. Hughes, had violated said Injunction by selling the "Hughes Acid Phosphate," so-called, and that a writ of attachment must issue against them, whereupon the said respondents were fined \$300 each.

The Rumford Chemical Works again warn all persons from selling any imitation of Horsford's Acid Phosphate, or any Acid Phosphate under any style of label, or form of package, for use as a medicine or article of diet, or ingredient to be employed in beverages or food; or any proprietary article for use as a medicine or beverage, under the name of "Acid Phosphate," as they will thereby infringe their trade-mark, copyright, or patents, and render themselves liable for damages.

With reference to the above, it affords us pleasure to note the prompt and vigorous action taken by the Rumford Chemical Works in this case, and the recognition by the Supreme Court of the rights of said corporation. The disreputable and growing practice of infringing upon well-known and meritorious articles, after they have acquired reputation, popularity and value, should be discountenanced by all respectable dealers, as it is by the Courts, and the attempts of unscrupulous persons to build up a business upon the capital of somebody else, and thus perpetrate a wilful fraud upon the community, should be everywhere condemned; and the trade, moreover, should do all in their power to protect the rights of individuals and corporations in the exercise of a legitimate business.

Clinical Lecture

ON A

CASE OF HYDATID DISEASE OF THE LIVER REQUIRING OPERATION;

WITH REMARKS ON THE MODES OF MIGRATION OF
EMBRYOS.

By THOMAS OLIVER, M.D., M.R.C.P. Lond.,

Physician to the Newcastle-on-Tyne Infirmary, and Lecturer
on Practical Physiology in the University of Durham.

GENTLEMEN—Most of you have seen with me in the ward upstairs a patient who was the subject of hydatid disease of the liver. By this is meant a condition in which the liver is the seat of a cyst or cysts in which are found echinococcus vesicles floating in fluid, these vesicles being the immature form of a parasite known as the *tænia echinococcus*. I will give you briefly the history of the case.

Edward S—, aged twenty-seven, an iron-roller from Middlesborough, was admitted into the Newcastle Infirmary on Oct. 30th, 1882, complaining of pain and a sense of fullness over the region of the liver. He is unmarried, and was a healthy man until two years and a half ago, when he began to feel pain in the right chest and a sense of weight in the right hypochondrium. He has never partaken of raw meat, but has eaten largely of pork and pork sausages. He is a great dog-fancier; at the present time there are five dogs at his home. The supply of drinking-water to his house is direct from the main, and there are no wells in the immediate neighborhood of his dwelling. The patient has a peculiar sallow look, and has lost considerably in weight. He is the subject of extreme constipation, but has never suffered from epistaxis or hæmorrhage from the bowel. He says that he had jaundice in boyhood, and that it lasted a very long time. Some time before the bulging appeared in the right hypochondrium he was obliged to seek medical advice on account of pain which he felt there. As the bulging increased, shortness of breathing came on, and he had distinct rigors. In the early part of October he was tapped by Dr. Hedley, of Middlesborough, and sixty ounces of clear serum withdrawn. For a few days he was somewhat prostrated, but the bulging disappeared.

Three weeks after the tapping rigors set in and the swelling returned, accompanied by a feeling of pain. On admission his abdomen was somewhat prominent and resistant to the touch, while the sides were rather bulging. From the level of the right nipple down to the lower margin of the lowest rib an absolutely dull percussion note was heard; a similar area of dullness was detected on the left side. Both were continuous in front, so that hepatic, cardiac, and splenic areas seemed to run into each other. The area of dull percussion measured eight inches vertically. The bulging affected particularly the right hypochondrium, for it measured one inch more than the left. Pain was more or less a constant symptom; it was increased on pressure over the epigastric and hypochondriac regions. A well-marked wave of fluctuation was detected over the right lobe of the liver. His urine, which was amber-colored and acid, had a sp. gr. of 1032, and contained just a trace of sugar. On examination, the chest above the level already mentioned exhibited nothing abnormal. Posteriorly, however, it was noticed that the dullness did not begin for at least two or three inches below the line noticed in front. Over the lower part of the right lung there was detected small moist crepitation; the same was noticed over the base of the left; otherwise the respiratory sounds were normal. The cardiac sounds were healthy.—On Nov. 8th, ninety-two ounces of a greenish-yellow fluid, having a sp. gr. of 1012, of alkaline reaction, and containing a large quantity of albumen, was removed from the right lobe of the liver by means of the aspirator. In this we found numerous hooklets, broken-down cells, and fat globules. The removal of the fluid was attended by a good deal of pain, and was followed by a feeling of prostration and a sense of coldness. A few days after the operation the patient felt remarkably well; the large area of dull percussion over the hepatic region had undergone great diminution. Over the area under the right nipple, where previously a dull percussion note was audible, there was clear percussion, and the breath sounds were distinctly heard, accompanied at the end of inspiration by small crepitation. On November 15th it is reported that the patient had suffered a good deal from pain in the abdomen and from headache. The temperature on the previous evening had reached 103.4°, and in the morning had fallen to 102.4°. There had been slight rigors during the night. His pulse was 120, skin hot, tongue coated, and his lips dry. His respiration was 36 per

minute, and he complained of shortness of breath, but there was no stitch-like pain in the chest or abdomen. There was a degree of tympanitic distension of the abdomen, and the area of percussion dulness was carried somewhat upwards. Under the administration of small doses of opium, effervescing mixture, and the application of poultices, the patient somewhat improved. The temperature fell to 100.4° and the pulse to 104; the breathing improved, but he still complained of feeling chilly. From this time onward the temperature oscillated between 100° and 103.4°. The pain in great part disappeared, but the dull area of hepatic percussion increased in all directions. Fluctuation was easily detected from right to left, or vice versa, and a coarse friction sound could be heard on auscultation over the region of the liver. Pressure of the stethoscope gave rise to great pain. It was noticed that the patient lay with his knees drawn upwards, and that he was gradually getting thinner, and was beginning to look haggard. By Dec. 4th the patient was suffering very severely from pain in the right side, extending round to the spine. The dulness on the right side extended from the second intercostal space down to an inch above the level of the umbilicus, and on the left from the third intercostal space to near the level of the crest of the ilium. Fluctuation was distinct, and there was marked bulging of each costal arch. There was evidently fluid in the peritoneum. The heart was felt beating almost in the left axilla, three inches above and two inches external to its normal situation. Bronchial râles were heard over the upper part of each side of the chest. It was now decided to cut down upon the liver and give free exit to its contents. Accordingly, two days after this, my colleague, Dr. Hume, performed the operation of abdominal section, with incision of the liver, taking care to stitch together the walls of the cyst and abdomen. A small quantity of serum escaped from the peritoneum. On incision of the cyst, which was partly adherent, seven pints and eight ounces of a thick purulent fluid escaped, in which we noticed shreds of a delicate membrane. While the fluid drained away the heart could be seen returning to its normal position. A drop of this fluid submitted to microscopical examination was found to consist of pus cells and a few rod-like bodies of a brownish color and with bulbar extremities; the membrane exhibited delicate lines running across a granular matrix. The operation was performed under antiseptic precautions, and for some time after similar care was given to the dressings. Beyond suffering from a little bronchitis the patient did remarkably well, nothing occurring worthy of note until Dec. 28th. On this and the preceding day thick pieces of membrane were discharged through the abdominal opening, particularly on coughing. About six ounces came away, evidently portions of the cyst-wall. It appeared to the naked eye to be composed of three layers—two outer, white and seemingly fibrous, and between these a brownish-yellow gelatinous substance. It had an offensive odor. Its surface was studded with small whitish nodules, varying in size from a pea upwards, the contents of which exactly resembled semi-coagulated albumen. Portions of this membrane placed under the microscope exhibited a well-marked stratified arrangement, not unlike fibro-elastic tissue. From this date onward nothing occurred, save an occasional attack of bronchitis, to mar the convalescence. Ere the abdominal opening contracted to the extent which you see it now, I had an opportunity of exploring the interior of the cyst by means of the electric light endoscope, and of observing that a granular condition existed similar to that which

is seen in the healing of large external wounds. No bad effects followed the illumination. The patient is about to leave the infirmary cured of the hydatid disease of the liver.

Those of you who have had a course of lectures on zoology will readily understand the meaning of the term "alternation of generation;" it is reserved for a feature in the life-history of many of the hydrozoa and entozoa, in which you have a condition of matters something like this. An organism, to start with, contains male and female organs, and as a result ova are developed within it. These ova, when liberated, develop into sexless forms of life, entirely unlike the organisms from which they sprang. Although sexless, they are yet capable of bringing into existence, by a process of budding, myriads of organisms like themselves, and these, again, by a process of budding extend the chain. A time comes, however, in the history of these immature forms when they change their character. They revert to the original bisexual type, and in this way exactly resemble the organism which started the chain. Such is the life-history of the echinococci which cause hydatid disease. They are the immature sexless brood of a parasitic worm known as the *tænia echinococcus*, and, like the sexless brood to which I have referred, they are capable of perpetuating themselves for a time by a process of gemmation.

Repeated examination in countries where hydatid disease is more or less endemic has caused the dog to be regarded as the victim of the adult worm, or *tænia*. The *tænia*, according to Cobbold, is a small cestode, seldom more than a quarter of an inch in length, and composed of four segments, the foremost of which is capped by a pointed beak and armed with a double row of hooklets. It is the fourth or final segment which is sexual. Mature links of the worm are discharged from the bowel of dogs thus afflicted, and by some means or other the ova find their way to drinking water or come in contact with food. Having reached the human stomach by means of these media, the ova lose their shelly covering and the embryos are set free. With their six hooklets they are said to bore their way into the organs of circulation, and in due time reach the liver, lungs, or brain. Ultimately they become fixed, and immediately thereafter begins the metamorphosis by which these embryos become hydatids. Spherical from the first, the hydatid becomes surrounded by a layer of connective tissue which is derived from the proliferating connective tissue in the neighborhood—rather that, I think, than a secretion from the hydatid itself. At this period the hydatid can be lifted from its bed of connective tissue. On examination it is found to be composed of a membrane enclosing a granular mass. From this granular mass is formed another membrane, more delicate than the other, and lined by nucleated cells. To these two layers Huxley has applied the term ectocyst and endocyst. With the outer of these two layers we have little to do; it is structureless, and is formed of a substance not unlike chitine. The endocyst, though only 1-2000 of an inch in diameter, is very important, for it is from it that all future development proceeds, the first indication of which is seen in the alteration in form which its layer of nucleated cells undergoes. From being flattened they become round, and afterwards elongated, and sooner or later, according to Leuckart, many of them are to be seen as small papillæ projecting into the granular mass. It is to these papillæ, the future scolices, that developmental activity is now transferred, further change in which soon follows upon vacuolation of their contents. A vacuole is detected in their interior, and in time this is

found filled with fluid. A stage further on and we find the cavity lined with a delicate cuticular membrane. Beyond this the further steps of development are with difficulty traced. Suffice it to say that each papilla becomes, after an increase in its size and alteration of its form, a true echinococcus head. At times it sacrifices itself, develops an internal germinating membrane similar to the one I have mentioned, from which arise papillæ, and from these again a brood of echinococci. These are the brood capsules that become the daughter vesicles, the parental name being retained for those from which they originated. We have then mother vesicle or original cyst, and daughter vesicles, the larger of which become free and float in the fluid of the mother cyst, while the smaller remain adherent to the wall, and may give rise to a brood of capsules, granddaughters of the original.

Compared with other countries we see little of the effects of echinococci. Not more than thirty-four deaths per annum are reported as due to hydatid diseases—a return which Cobbold is inclined to question, four hundred being, in his opinion, nearer the truth. Even with this higher mortality the death-rate is simply nothing compared with that in others countries. In Iceland, for example, where the disease is so frequently met with as to be considered endemic, it is said that one-sixth part of all the inhabitants annually dying fall victims to the echinococcus epidemic. Australia a few years ago gained for itself a reputation for its high death-rate from hydatid disease. None of the inhabitants of that continent seemed to be exempted: the rich suffered equally with the poor, the shepherds on the plains with the miners underground. As for Iceland, there is something peculiarly unique in its geological conditions which render it a fertile soil for the development of these parasites, especially, too, when taken with the fact that the peasantry of that island maintain a very close intimacy with dogs. Without these animals it is impossible that the disease could be contracted. The possessor of several dogs, the Iceland peasant shares with them his compartment, and allows them to eat off the same plate with himself. Not less than 28 per cent. of these animals are effected. With this relationship maintained between peasant and dog in an island possessing hot springs, etc., and with the river-water warm, which is the source of drinking-supply to the inhabitants, who are heedless of sanitary arrangements—with these facts before us we have sufficient explanation as to the prevalence of hydatid diseases in Iceland. One point, too, is of interest, and it is this. According to Schel-eisner, hydatids are more frequently met with amongst women than men in Iceland, and this can only be explained by the different habits of the sexes. The water which the women use for drinking is obtained from supplies in the immediate neighborhood of their dwellings, from places to which the dogs have easy access, whereas the men are engaged in fishing or hunting, in pursuits, at least, which take them away from the immediate vicinity in which they live, and, as a consequence, they suffer less.

It is noteworthy that certain organs in the body are affected more frequently than others. Taking my statistics from Cobbold, it appears that out of a total of 700 authenticated cases, the liver has been affected 326 times; the lungs have been affected 62 times; the kidney and bladder, 53 times; the brain has been affected 42 times; the bones have been affected 33 times; and the heart and vessels, 25 times.

Briefly, the liver is affected in 46½ per cent. of those who suffer from hydatid disease; the brain

in 6 per cent.; and the heart in 3½. These facts are not, I think, satisfactorily explained by the ordinary theories; bearing upon the migration of embryos. Niemeyer and other authors maintain that once the echinococcus ova or embryos have been discharged from the bowel of the dog and have entered the human intestine, the embryos, freed from their capsule, bore their way by means of their six hooklets through the wall of the stomach or intestine, and, wandering further, finally reach the liver, where they develop subsequently into a true hydatid cyst. I do not question the possibility of this occurring. It is mentioned by so many writers of note that it is probably one of the modes of migration. But what are we dealing with? We have a microscopic object armed with six hooklets, and we are told that by means of these it bores its way through the wall of the stomach or intestine, and such a thing as the capsule of the liver. To my mind the difficulties to the progression of the embryos are by this mode so very great that there must be other channels by which they travel. I do not say that this mode of migration is an impossible one; for we know that parasites travel long distances under the skin. All I say is that the establishment of embryos in the various organs is not always due to their own propelling powers. Echinococcus ova or embryos swallowed along with food, or imbibed with drinking-water, having reached the stomach, are therein subjected to the chemical and triturating process of digestion, the immediate effect of which is the dissolution of the envelope, and the liberation of the embryo. The probabilities are that the embryos do not remain in the stomach any length of time. They pass on into the intestine along with the rest of the food. From the stomach, then, the chances are that the embryos do not make their way by boring into the tissues. They leave the stomach along with the chyme and pass on into the intestine. It is in this part of the digestive tract that the food lingers longest, and consequently it is from it that the embryos pass out into the various organs, their progression accomplished not by boring, unless it be into the venous radicles of the intestine, which pour their contents into the vena portæ. In this way they may reach the liver. By means of the venous system therefore many echinococcus embryos reach the liver, and there they develop into hydatid cysts. The work of preparing tissues at the College for the class of practical physiology has given me many opportunities of detecting scores of ova of parasites, probably of the distoma or fasciola hepaticum in the villi of the intestines of rabbits; and further examination of the liver in the same animal has shown the deposition of ova in that organ. I have been struck by what seemed to be a coincident deposition of ova, or what might more accurately be described, because I believe this is what takes place, as a rapid appearance of ova in various parts of the liver while the intestinal villi remained here and there full of them. This, and the additional fact that the liver is in both cases the seat of parasitic selection, lead me to believe that the mode of migration of embryos must be the same. The echinococcus embryos, according to this view, find their way into the intestinal villi in the first instance, thence into the lymphatics, or more properly speaking the lacteals, which run at the base of the villi, and as these pour their contents, interrupted no doubt in many cases by lymphatic glands, into the thoracic duct they easily reach the blood; hence the explanation of hydatid disease of lung, brain, kidney, etc. If their onward course is interrupted by the intervention of a gland, then we have them deposited

there, and an explanation of hydatid disease of mesentery. From the intestinal venous radicles into which echinococcus embryos may have got by boring, not an unlikely thing, they easily reach the liver, but I see no reason why they, too, do not reach that organ by means of the lymphatics. Lacteals and lymphatics are continuous, and I see from Quain's Anatomy that the deep lymphatics of the liver join, at the side of the coeliac artery, one of the large lacteal trunks, previous to its terminating in the thoracic duct. If the intestinal villi are the easiest mode of ingress for parasitic ova or embryos, as I think they are, since it does away with the idea of propulsion by their own efforts, then by means of the lymphatic connection which I have shown, the liver would be the organ first reached, because most of the upper intestinal lymphatics pour their contents into large lacteal vessels, and do not communicate with lymphatic glands. Transference of parasitic ova from the intestine is accomplished through the lymphatics. Such a mode of migration not only explains why the liver is in the largest number of cases the organ affected, but it also explains those other cases of hydatid disease of mesentery, and also through the medium of lymphatics, thoracic duct, and subclavian vein, hydatid disease of lung, brain, and kidney. I fail to see how any amount of boring on the part of echinococcus embryos will explain the fact of the right lobe of the liver being most frequently the seat of the disease unless it be by boring into venous radicles. Taking everything into consideration, however, I regard the lacteals of the intestinal villi as the medium by which parasitic ova gain admission into the economy.

Another question of interest crops up in the development of hydatids. The drinking of water contaminated by echinococcus ova, or the eating of raw meat infected with these embryos, is in many cases followed by the development of hydatids in man; and in the case of dogs in Iceland, if these hydatid vesicles are eaten the mature worm or tænia is the result. Suppose man, however, should swallow hydatid vesicles, would he develop the mature worm? There is no instance of this recorded, so far as I know; and yet portions of hydatid vesicles must have tainted the food or drinking water of men in countries where the disease is more or less endemic. Knochenmeister considers it not improbable that echinococci, reaching the bowel of a person in whom hydatids exist, develop tænia. I am not sure that man ever develops the tænia. Our knowledge of his relationship to the parasite is that it is the vesicular condition we meet with. There is no absolute reason why the vesicular stage should not be repeated in man. I quite think with Davaine that the hydatid corresponds to a phase in the development of an animal which lives a certain period and which may be produced a certain number of times under the vesicular form. Reverting to my remarks on alternation of generation, you observe a resemblance to the intermediate phase there spoken of.

Trousseau says that the absence of albumen is a distinctive feature of the fluid taken from hydatid cysts. On the first occasion we aspirated S—we removed a thick, greenish, ropy fluid, which contained a very large quantity of albumen. The cyst had previously been tapped by Dr. Hedley, who kindly sent me the patient, and consequently we had to deal with, not the ordinary fluid of a hydatid cyst, but of fluid which was in great part the secretion of a cyst somewhat inflamed.

Of the treatment of hydatid disease of the liver I need say very little. Medicine can do but little good. The removal of the fluid which bathes the

vesicles, and probably nourishes them, is the surest mode of destroying them. Frequently one or twoappings by means of the aspirator will suffice; when it fails, it may, as it did in this case, set up suppuration of the cyst, and require free incision—a procedure not without danger, although most cases, I think, end favorably.

Clinical Remarks

ON

ABSCESSSES IN THE UPPER PART OF THE ABDOMEN.

Delivered at St. Thomas's Hospital.

By JOHN S. BRISTOWE, M.D., F.R.S.,

Senior Physician to the Hospital.

GENTLEMEN—Cases of abscess arising in the upper part of the abdominal cavity are always extremely interesting, for their diagnosis is generally difficult, and they are often not only sources of anxiety to the medical man, but attended, as regards the patient, with much distress and danger. The cases which I am about to recount and comment upon are remarkable in these respects. The first was very instructive, at any rate to myself. It was that of a young woman who, a few years ago, was transferred from the Westminster Hospital to my care here, at the time when that institution had to be closed for the purposes of cleaning and alteration. She came to me with the history that she had been suffering from ulcer of the stomach, that perforation of this viscus into the peritoneal cavity had taken place, that she had consequently had sudden and intense peritonitis, of which she had nearly died, but that her acute symptoms had subsided, and that there had been for two or three months slow but on the whole progressive amendment. On admission her symptoms suggested to me that she was suffering from general tuberculosis, with special implication of the peritoneum. It is true that cases of recovery after rupture of the stomach into the peritoneal cavity are recorded, and especially I recollect that one such apparently undoubted case was published many years ago by the late Dr. G. H. Barlow, of Guy's. But knowing that recovery after such an accident is one of the rarest incidents in medicine, and never to be admitted in any case without the strongest evidence in support of it, I was naturally predisposed to disbelieve in the diagnosis made at the Westminster Hospital, and am afraid that I did not hesitate to express myself irreverently with respect to the diagnosis of the distinguished physician under whose care she had been. I know, indeed, that I repeatedly pointed out that the symptoms she presented on admission into St. Thomas's were exactly such as one observes in tubercular peritonitis, and that, taking all things into consideration, it was much more probable that the acute attack she had had some months before, and which had been attributed to perforation, was an accident, so to speak, of her abdominal tuberculosis, and had been misinterpreted. Her progress while under my care seemed to accord with my diagnosis; and the fact that she had a slight cough, attended with some indications of mischief at the apices of the lungs, and that shortly before her death she expectorated some very fetid fluid, amply, as I thought, confirmed it. Now, at the post-mortem examination there really were found tubercles in the peritoneum and tubercles in the lungs; and so far, of course, I was

right. But I could not help admitting that the tubercular disease was not sufficiently advanced to have caused her death, or even to have been the chief factor in the causation of her symptoms. And, indeed, we found something more. We found that she had had an ulcer of the stomach, and that this had perforated the organ; and we found further that a circumscribed abscess between the stomach on the one hand, and the under-surface of the liver and diaphragm on the other, had resulted from the perforation, and that the fetid matter expectorated from the lungs shortly before death had been derived from the abscess, which had opened through the diaphragm into the base of the left lung.

It will be admitted, I think, that my diagnosis was not quite unjustified by the event, and that even the expectoration of stinking fluid was, on the whole, calculated to confirm me in my opinion of the case. But I am bound to confess that I failed to recognize or admit the main facts of the case, and to acknowledge that the physician under whose care the patient was originally was essentially correct in his views, and that he deserves high credit for both his accurate diagnosis and his skilful treatment of a very obscure and interesting case. I take off my hat to Dr. Sturges, and promise never again to treat his medical opinion with disrespect.

CASE 1. Perforating ulcer of stomach; rupture into peritoneal cavity; formation of circumscribed abscess between liver and stomach, subsequently opening into the lung; miliary tubercles in lungs and peritoneum; death; autopsy.—Ellen R. H.—, a girl nineteen years of age, was brought from the Westminster Hospital and placed under my care in St. Thomas's on June 18th, 1877. Her history was that she had been suffering for some time from ulcer of the stomach, with vomiting of blood, and that she had been three or four times in the Westminster Hospital for that malady; that last March she was sent thence to the Convalescent Home at Walton; that while there she was attacked suddenly with severe epigastric pain and faintness, and was consequently brought back to Westminster Hospital; that on readmission she had extreme general abdominal pain and tenderness, with tympanites, vomiting, collapse, and other characteristic signs of peritonitis of a very severe form. It was assumed that perforation of the stomach had occurred at the seat of ulceration; but under judicious and careful treatment she emerged from her condition of collapse, and the more acute of her abdominal symptoms subsided. Since that time her condition has varied a great deal, and she has remained very ill and weak, but on the whole has improved. She has been sick at times, and has had a slight cough. On admission into St. Thomas's she was anæmic, emaciated, and very weak. Her abdomen was tumid, tense, tympanitic, and tender on pressure; and she suffered from pain and uneasiness in it. Her tongue was coated; she was thirsty, frequently sick, and had little appetite. There was no marked dulness at the apices of the lungs, but there was a little variable subcrepitation, and a little wheezing over the rest of the lungs. Pulse 100; respiration 24; temperature 100.2°. There was no further evidence of disease. She was treated with ice to suck, a mixture containing bismuth, and nutrient enemata. She remained very weak, perspiring profusely at times, and presenting a temperature which usually varied between 101° and 103.5° down to July 9th or 10th. But, notwithstanding, she seemed to improve; her sickness diminished, she took food by the mouth, felt stronger, was able to sit up in bed, and looked bright and cheerful. At this time her tongue was clean; her chest was resonant, but there was a little subcrepitation and

wheezing at both apices, most at the right, and at the left base; she had a little dry cough; and the abdomen was only slightly tumid and tender, mainly below. Soon after this, however, a change for the worse occurred, and on the 12th or 13th her cough became very troublesome, and attended with copious expectoration of a very offensive, turbid, brownish fluid. Her tongue remained clean, but she lost her appetite again, her pulse rose in frequency, she became excessively weak, and, continuing to the last to spit up large quantities of the fetid fluid above described, died exhausted on the morning of the 16th.—Autopsy: The lungs were studded with miliary tubercles, and the peritoneum presented abundant old adhesions with scattered tubercles of the same kind. Between the stomach below, and the under surface of the left lobe of the liver and the diaphragm to the left of this above, was a flat abscess-cavity occupying an area about equal to that of the hand. It was bounded elsewhere by old adhesions. Its parietes were dirty-looking and flocculent, and it contained a small portion of fluid resembling that which had been coughed up during life. This cavity communicated on the one hand with a small perforated ulcer situated at the posterior part of the stomach, near the pylorus, and on the other by a fistulous opening, through the diaphragm and adherent pleura, with the base of the left lung. The gastric ulcer was small and quiescent; the orifice in the base of the lung was irregular and flocculent-walled, and was the channel by which the contents of the abscess had been recently evacuated. All other organs were healthy.

The second case was also one of much interest, and one in regard to the exact nature of which I was long in doubt. The patient was a young married woman, who for eighteen months before I saw her had been suffering from pain in the splenic region, and who had had rigors. On admission into the hospital she presented a tumour of considerable size in the situation of the spleen, which differed from the spleen apparently only in the facts that it was distinctly adherent to the abdominal parietes, and consequently moved only with them, and that its anterior edge was obtuse, and presented no notch. The patient was very weak and ill, and during the ensuing two months or more complained of a good deal of pain and throbbing in the region of the tumour, which remained stationary; she presented a very fluctuating temperature of hectic type, which often rose above 105°, and on one occasion reached 106.8°, and, on the other hand, frequently descended to the normal, and even below that; she had occasional rigors, and suffered from nausea and sickness, from alternations of diarrhoea and constipation, and from occasional pains in her limbs. Moreover, the urine at times presented traces of albumen. In the early period of my treatment of the patient I had some inclination to think that her symptoms were due to malarial poisoning, although the apparent incorporation of the tumour with the abdominal walls was adverse to the view that the tumour was simply an "ague-cake." Before long, however, I began to suspect the presence of multiple embolism, with special implication of the spleen: an interpretation of the case which seemed in accordance with the peculiarities of the temperature, and most of the other phenomena above enumerated, but which the absence of obvious heart disease contra-indicated. It must be borne in mind, however, that vegetations are not unfrequently present on the auricular aspect of the mitral valve, and on the adjacent walls of the auricle, which cause no interference with the due action of the valve, and are consequently unattended with murmur. Later, it was concluded

that suppuration was going on; but the continued hardness of the lump, the total absence of fluctuation or even of any yieldingness, and its invariableness as regards size and shape, threw some doubt on this opinion. The view to which there was an inclination at this time was still that the patient was suffering from multiple embolism; but that some of the infarcts, which were presumably present in the spleen, had broken down, and were suppurating. A week or two before death some important changes took place in her condition. Diarrhoea came on, but the character of the stools unfortunately was not noted; she vomited a yellowish fluid of the consistence of gruel, with a manifest faecal smell; and about the same time the tumour almost wholly disappeared. Finally she brought up from the stomach solid lumps of faeces. It had now become perfectly clear that there had been an abscess in the situation of the supposed tumour, that it had opened both into the colon and into the stomach, and that a pretty free communication had become established between these viscera. The post-mortem examination showed little more than the correctness of this last inference. I assume, however, from the appearances found that the disease had begun in the colon, and that the inflammatory lump simulating the spleen was in some way or other (probably by the formation of a circumscribed peritoneal abscess) secondary to the intestinal disease.

CASE 2. *Abscess in the splenic region, between stomach and transverse colon; communication between these viscera; vomiting of solid faeces; death; autopsy.*—E. C., a married woman, aged twenty-seven, was admitted under my care on July 21st, 1880. She had had no illness of any importance, and there was no suspicion of syphilitic taint. She had had six healthy confinements. She first complained of illness eighteen months previously, just after the birth of her fifth child. At that time she began to suffer from pain in the left side, between the ribs and the crest of the ileum. There was tenderness, but, so far as she knew, no tumour. About that period, too, she had attacks of shivering. The pain and tenderness have never left her, and she has gradually lost flesh. Two weeks ago (July 8th) her last child was born, since which time the pain in her side has been much worse, and a tumour has been discovered in the splenic region. The pain has been of a throbbing and shooting character. She had some rigors before her confinement, but none since, until the day of admission. She had become very weak, had lost appetite, and vomited frequently. There had been no cough, no disturbance of the bowels, and no unhealthy symptoms referable to the reproductive organs. The patient on admission into the ward looked careworn and ill; tongue furred. In the splenic region was a hard tumour which did not move with respiration, and which seemed to be adherent to the parietes. It extended, in the mid-axillary line, four inches and a half below the ribs, and thence towards the median line of the abdomen, which, however, it did not reach. The general surface was rounded, its edge was obtuse, and presented no notch. It was dull on percussion, and dulness, continuous with it, extended to three inches and a half above the ribs in the mid-axillary line. The liver appeared to descend a little below the ribs. There was a little fine crepitation at the base of the left lung on deep inspiration. All the other viscera were apparently healthy. Urine 1015, no albumen. For the next four weeks her symptoms presented slight fluctuations, and on the whole improved. During this time the swelling underwent little or no change in size, but remained painful and tender, and at times she felt much throbbing in it. It continued hard, and

with no sense of fluctuation. Her appetite was bad, and she was occasionally sick; her bowels were confined; her temperature was very irregular, varying from 99° to 103.4°; and from time to time she had a rigor. There was a good deal of improvement, however, from the 11th to the 17th, during which time the temperature never rose above 99.5°, and was generally either normal or subnormal; the pain and tenderness also diminished. On the 18th her temperature rose from 101.6° in the morning to 103° in the afternoon, and she was very ill. During the next ten days she remained in the same condition. Her temperature presented the hectic character, rising on several occasions above 105°, and once to 106.8°, and often falling to the normal, or even to 97°. She had frequent rigors, and occasional pains in her limbs. Her appetite failed entirely, but she did not suffer from sickness. On the 24th she passed a small clot of blood with her motions, but she had no diarrhoea. The urine, which was of rather high specific gravity, contained a trace of albumen. She became exceedingly weak, prostrate, and very anæmic. It was observed that the lump remained about the same size, without bulging or fluctuation, and that its anterior and lower margin was distinct. After August 28th the temperature only once reached 105°. It fluctuated a good deal, however, and, excepting that she got manifestly weaker, she seemed on the whole to improve. On Sept. 4th and 5th she suffered from diarrhoea; but the character of the stools is not recorded. On the 4th, after feeling nausea for some time, she vomited about a pint and a half of yellowish-colored fluid of the consistence of gruel, with an offensive faecal smell. On the 9th she vomited half a pint of greenish fluid. The bowels continued to be moved freely. About this time the pain and tenderness in the region of the tumour diminished greatly. And on the 24th the following note was taken: "Patient weak; appetite very bad; no vomiting; no tenderness or pain in the region of the tumour; and all that can now be felt of the tumour is a cord-like hardness about the size of the finger, extending vertically downwards from the cartilages of the ribs." She continued from this time henceforth to be free from pain or material tenderness in the left side; the region of the tumour became resonant, and no indication of its presence, beyond the band just referred to, remained. Her temperature moreover became normal, and latterly even subnormal, and there was no recurrence of rigors. But pains, apparently rheumatic, affected the joints of her lower extremities, mainly those of the right side; her appetite remained very bad; and she steadily lost flesh and strength. She vomited occasionally, and a few days, eight or ten perhaps, before her death she brought up for the first time solid lumps of unmistakable ordure. This was repeated on several occasions, and was regarded as a clear proof that some direct communication had become established between the stomach and the colon. She died on Oct. 12th. It may be added to the above account that there was never any sign of heart disease, or of change in the constitution of the blood, and, as regards treatment, that in the early part of her residence in the hospital a few leeches were applied over the tumour on several occasions, and also poultices; that when the temperature was excessive quinine and salicylic acid were both tried in large doses without material effect; and that generally she was treated with tonics and opiates. Post-mortem examination: On opening the abdomen a large, irregular, shreddy-walled cavity was found in the left hypochondriac region, between the left extremity of the transverse colon and the cardiac end of the stomach, bounded above in part by the

left lobe of the liver and in part by the abdominal parietes in the left hypochondrium. It contained shreds of tissue and blood, but no pus. It communicated freely both with the colon and with the stomach. In the transverse colon, near its splenic flexure, was an area of deep ulceration, surrounding the gut, and measuring about two inches and a half in length. Its edges were thick and spongy, but there was no evidence of new growth. The orifice of communication with the cavity was towards its posterior part. The openings into the stomach were several ragged holes clustered together, and had evidently taken place from without. The mucous membrane around them was quite healthy. The liver and spleen were healthy, and no other viscera presented any evidence of disease.

In connection with the last case I may recall the facts of another (Case 3) that was under my care in the hospital some years ago, but of which unfortunately the notes have been mislaid or lost. The patient was a tall young man, of about nineteen, with rickety curvature of the tibiae and other bones. He had, however, generally had good health, until, I think, a few months before I saw him, when he began to suffer from pain and tenderness below the left ribs. He went for a time into one of the large metropolitan hospitals, and there the tumour which was discovered in the splenic region, was taken for the spleen. On his discharge at the end of a month or two no material change had taken place in his condition, and his disease was still assumed to be splenic enlargement. On admission into St. Thomas's a tumour was recognized, which from its situation and form might certainly have been taken for the spleen. But it was as in the last case, unaffected by the movements of the diaphragm, and evidently adherent to the abdominal walls. So far the case was an almost exact counterpart of the one just narrated. But there were also manifest bulging of the lower ribs on the left side and of the adjacent part of the abdomen, and a great sense of resistance: phenomena which are always strongly suggestive either of an abscess or of a new growth, and of its incorporation with superficial parts. Accordingly I came to the conclusion that the patient was suffering from a new growth or abscess, arising in the spleen or its neighborhood, but involving the abdominal walls. I forget whether there were any additional facts in his history, or any peculiarities of temperature or symptoms when he first came under my care, to lead me to prefer one of these alternative views to the other. I also forget whether I was tempted make an exploratory puncture for diagnostic purposes. But I know that after a time I had an incision made into the swelling, that a large quantity of thick pus was evacuated, and that at the end of a few weeks the patient left the hospital well.

I do not know that one learns any very important special lessons from the above cases. But there are two or three points suggested by them to which I may call attention in a few words. In the first place, in the two cases that ended fatally, the cause of the circumscribed peritoneal suppuration was found to be perforation of one of the hollow viscera. It may be assumed, from this fact, as well as on other grounds, that abscesses in the upper part of the abdomen, not due to abscess of the liver, are largely dependent on this cause. In the second place, all the cases suggest the importance of evacuating the contents of abscesses in this situation as early as possible. Abscesses here, if left wholly to nature, are liable to burrow in various directions, to discharge themselves into and through various organs, and to lead in the course of their extension to irreparable mischief.

By a free external opening made at an early period such disastrous consequences would obviously be to a large extent averted. And, in the third place, it seems clear that the recognition of abscesses in the upper part of the abdomen is often extremely difficult, if not impossible, and that to diagnose them correctly demands the most careful and continued observation, and to treat them effectively calls for both skill and courage. I make these latter remarks without intending to imply that in dealing with my own cases I showed conspicuously any of the qualities here specified.

I venture to add, in conclusion a brief account of a post-mortem examination which I made many years ago on a girl whose case in many respects obviously resembled that with which I commenced my lecture. Unfortunately no clinical account has been preserved. But the post-mortem record shows clearly that she had an ulcer of the stomach, which had perforated that viscus; that as a result of this perforation circumscribed peritonitis had ensued, with the formation of fetid pus in the neighborhood of the spleen; and that the circumscribed abscess had both penetrated into the substance of the spleen and perforated the diaphragm. It is interesting, however, to note that the fetid abscess was separated from the perforation, which had doubtless caused it, by a tract of simple inflammatory adhesion; that although the abscess had perforated the diaphragm there was reason to think that inflammatory changes which were present in the chest had not been caused by this perforation; and that gangrenous cavities whence fetid pus might well have been expectorated were present in the bases of both lungs. The case is further interesting because the abscess connected with the spleen was mainly in front of it, and must, if it had been recognized during life, have presented the local features exhibited in my last two cases.

CASE 3.—C. H—, a girl, aged eighteen, was admitted into St. Thomas's Hospital on March 27th, 1854, and died there on April 6th. At the autopsy the pericardium and heart were found to be healthy. The lower lobe of the left lung was adherent to the diaphragm and sides of the chest by a layer of recent lymph; it was more solid than natural, congested, and soft, and presented numerous patches, from the size of a filbert downwards, in which the tissue was solid or broken down into a stinking gangrenous pulp. The upper lobe of the left lung was healthy. The upper and middle lobes of the right lung were healthy, but the lower lobe was in the same condition as the left lower lobe, though less extensively affected, and recent lymph was deposited on its surface. Abdomen: All the peritoneal membrane below the stomach and great omentum was healthy; but the left lobe of the liver was attached to the diaphragm by recent adhesions, and the under surface of the anterior half of the right lobe, and the whole of the under surface of the left lobe were similarly united to the anterior surface of the stomach and to the spleen. On separating the liver from the stomach, a circular opening, about half an inch in diameter, was found in the anterior wall of the stomach close to its lesser curvature and midway between the oesophageal orifice and the pylorus. On separating the spleen from the parts surrounding it a circumscribed cavity was laid open, the walls of which were formed by the anterior half of the spleen, the diaphragm, and the cardiac end of the stomach. This cavity contained a considerable quantity of thick greenish fetid pus and was lined by soft discolored lymph. It was further found that a diverticulum of the abscess extended into the substance of the spleen, and that a little above this point the dia-

phragm presented several perforations due to ulceration. Direct communication between this abscess and the pleural cavity appeared to have been prevented by adhesions between the diaphragm and ribs; and further no direct communication could be traced between it and the ulcerous perforation of the stomach. The mucous membrane of the stomach was generally healthy, but at the seat of perforation it was destroyed to a considerable extent. The ulcer was one of the ordinary character, and partly cicatrized. All the other organs were healthy.

An Inaugural Address

DELIVERED IN

UNIVERSITY COLLEGE, LONDON,

On Oct. 1st, at the Opening of the Session 1883-4,

By PROFESSOR JOHN TWEEDY, F.R.C.S.

GENTLEMEN—As the spokesman, for the nonce, of the Medical Faculty of this College, my first duty is to give you all a hearty welcome; not less to you, old friends, who, mindful of the happy associations of former years, grace these proceedings by your presence, nor you who are the actual participators of our current labors, than to you, young scions of a hopeful race, who are, here and now, to be engrafted upon an ancient and honorable stock. It is, indeed, to celebrate your initiation into the medical profession that we are chiefly gathered together; and custom has prescribed, and good fellowship enjoins, that the occasion should not be allowed to pass without our giving you the assurance that you have here friends to greet you, hands to help you, and willing hearts to serve you. Let me, then, congratulate you on the choice you have made of the profession of medicine as the sphere of your labors, and of this College as the place of your studies.

Whatever may have been the considerations which have led you to enter the medical profession—whether the accident of birth, social relationships and family ties, or the exercise of a deliberate choice—it is not likely that you and your friends have selected this college without some thought and inquiry. This circumstance might seem to render it unnecessary for me to attempt to add strength to your convictions; but I cannot forbear from dwelling upon some of the special advantages which I believe will accrue to you from studying in this place. No vindication is needed of the general scope and character of the education that University College affords. The continued and unvaried success of half a century is a sufficient testimony to its efficacy and its worth. Scarcely a city, town, or village throughout the British Empire but cherishes one or more of her sons. They sit in seats of honor in high places; Royalty calls in their aid; the State avails itself of their knowledge and acumen; Science applauds their genius; Learned Societies award them enviable honors; and Schools of Learning accept their co-operation with delight. The practical sagacity and the true political insight of the founders of this College, the energy and enthusiasm of our predecessors, and the enlightened enterprise of our executive body, have furnished many of the elements of our success. Our museums, laboratories, class-rooms, and libraries, afford facilities of observation, study, and research, which in their entirety are unsurpassed by those of any medical college in the world. Our hospital has supplied the material of the public

experience of some of the greatest teachers and practitioners of this age. It has been the scene of the clinical and scientific achievements of Elliotson, of Anthony Todd Thompson, of Robert Carswell, and of Samuel Cooper; and, among those, happily, still living, of C. J. B. Williams, of Walshe, of Jenner, and of Reynolds; of Richard Quain, of Erichsen, of Henry Thompson, and of Wharton Jones. Here, too, Liston performed those marvellous feats of surgical skill and daring that made him the wonder and delight of his contemporaries, the envy and despair of his successors. But it is not only in the practical departments of medicine and surgery that University College has been renowned. From this college and hospital have emanated some of the most famous and permanent contributions to medical literature. The comprehensive Surgical Dictionary of Samuel Cooper, the classical treatise of Erichsen on the Science and Art of Surgery, that fund of clinical record blended with philosophical reflection in Walshe's works on Diseases of the Heart and the Lungs, and Quain's copious and authoritative text-book of Anatomy, had their birth and have received most of their nurture within this fold. Nor have we been behindhand in the higher departments of scientific thought and investigation. This college has, from its very foundation, been distinguished from most other medical schools by the plan and method of its studies. Its guiding principle has been to teach by great authorities, by specialists and experts in their particular departments of learning. This has given to its teaching a thoroughness, reality, and dignity that have enabled a large proportion of its pupils not only to excel as practitioners, but also to attain distinction as students of science. Nor have these results been casual or fortuitous; they have been, rather, the anticipated culmination of a sagacious and well-regulated system.

There is a collateral advantage, amounting almost to a privilege, which the medical student in this college may enjoy. This institution is not a medical school only; it is a large educational establishment, embracing also the Faculties of Science and Arts, and employing the services of men eminent in every department of thought. Its range of studies is therefore wide and encyclopædic, and exhibits many of the social and intellectual characteristics of a university. Though a student cannot, of course, pursue every subject that is open to him, even in his own Faculty, and still less in other Faculties, he cannot fail to be a gainer by living among those who represent the entire circle of knowledge. He breathes an intellectual air, and profits by traditions which are independent of particular teachers. Though the relationships between the students in the medical and other faculties have not always been so close and so harmonious as might have been wished, there are real and substantial benefits to be gained by a freer intercourse and a closer intercommunication. In the Faculties of Science, and of Arts and Law, you will find many earnest and anxious toilers after truth, who are doubtless destined to take high places among the thinkers and the workers of the immediate future; and it is to your intellectual and moral advantage, to say nothing of your social interest, to make the acquaintance of such, and to grow up in friendly communion with them.

Though I have given precedence to your connection with University College, I would not have you suppose that I regard this as the permanent order of relative importance. While I wish you to cherish sentiments of affection and loyalty to this college, I am not so devoid of the sense of relativity as to

place this institution in the forefront of your thoughts. It is Medicine, its aims and aspirations, that is to be the absorbing passion of your lives. You are to be medical men first, and University College men afterwards. To this end it is necessary that you should have clear notions of what Medicine is, in order that you may comprehend its character, be faithful to its traditions, and zealous for its honor and advancement.

What, then, is Medicine? To most of you it may at present seem enough to call it the art of diagnosing disease and prescribing remedies. It is this; but it is something more. Medicine is essentially the Science of Health. So long as the idea of medicine was limited to the study and treatment of disease, its progress was slow and uncertain, and its place in the hierarchy of intellectual pursuits doubtful and ill-defined. Now, however, the medical profession would still retain the most important part of its duties, and all, or more than all, its present share of honors, if every drug in the Pharmacopoeia were to become extinct. The credulous faith in the efficacy of drugs is, and always has been, the secret of the success of every form of charlatanism. Medicine, then, being not merely the art of healing, but the science of life in its organic relations, the duty of studying and investigating the phenomena and conditions of health becomes paramount. It was the recognition of this truth that raised Hippocrates and his school out of the region of mere empiricism. Before his time, medicine in Greece had been cultivated in the priestly schools of the Asclepiadæ, and had remained a mere technical craft, based upon hereditary experience. But Herodicus, who is said to have instructed Hippocrates in the use of gymnastics in the treatment of diseases, sought to fix the rules of a scientific promotion of health. Inquiry was instituted into the influence of various nutriments and ways of life, and thus was created a new art, which had reference, not to the treatment of particular diseases, but rather to the invigoration and preservation of the human organism as a whole. The efforts of Hippocrates and his followers were, however, rather to promote the health of individuals, whereas the aim of modern medicine is, in addition, to conserve and protect the health of communities. Imagine the condition of a large city like London, with four millions of persons congregated upon the comparatively small area of a hundred and twenty square miles, without the sanitary and other resources which medical science has bestowed upon civilization. What a light has hygiene thrown upon the relations existing between the character of the soil, drainage, light, ventilation, food, water, clothing, and occupation, and the origin and spread of disease. Consumption, pneumonia, typhus and typhoid fevers, various epidemic and endemic diseases, malaria, dysentery, gout, and paralysis of many forms, are now known to depend upon preventable physical conditions. Small-pox, which up to the beginning of the present century inflicted such ravages, and even now makes frightful havoc upon unprotected communities, has been rendered practically eradicable by the means of vaccination. Cholera, as we have lately had experience, has not for us the terrors which it had for our fathers; its conditions have been ascertained, its secret discovered, and its malignancy disarmed. The experimental investigations of pathologists—and among them those of our Holme Professor of Clinical Medicine, Dr. Wilson Fox, have an honored place—aided by the beautiful microscopical researches of Koch, are elucidating the causes and origin of consumption, and have already kindled eager hopes of its effectual prevention.

The scope of medicine is therefore far-reaching, and in order to comprehend the whole science of medicine in the sense just defined, as the art of treating disease and the science of health, it is necessary to premise the study of the natural behavior of living matter—that is, Physiology. Strange as it may appear to uninitiated minds, the grandest discovery and generalization of modern medicine is that disease is healthy action gone wrong, or, as Mr. John Simon has described it, "Pathology consists in the science of life under other conditions than those of ideal perfection." Physiology is therefore the true foundation of medicine. This may seem heterodoxy to those who have been brought up under the influence of the older doctrine that anatomy is the basis of medicine. True, anatomy is indispensable to the study of Physiology; but anatomy is notoriously incapable of solving the simplest biological problem. Dr. Daremberg, in his learned history of the medical sciences, has observed that an examination of the history of medicine shows that the fate of pathology is bound up, scientifically and historically, with the fate of physiology; and that anatomy has not only at all times failed to reform physiology, but that ancient physiology, which was for the most part only a tissue of *a priori* speculations, has not unfrequently contributed to corrupt anatomy. Modern physiology has, however, amended itself by the experimental method, and henceforth is not likely either to miss its own way or to allow anatomy to go astray. On the contrary, it has opened up for anatomy new paths, and has, at the same time, furnished more solid bases of support for the reform of pathology. Do not mistake my meaning. I do not wish to say anything that can in the smallest degree be construed as depreciating the *absolute* value of anatomy. I merely protest that its *relative* rank needs to be readjusted. Anatomy is of primary importance to the study and practice of medicine; it is the very A B C, without which no real progress can be made. As without an acquaintance with the alphabet there can be no literary culture, so without anatomy there can be no medical attainments. Were it not for this, and for the help which a knowledge of topographical anatomy renders to the operating surgeon, the educational value of human anatomy, consisting as it does almost exclusively of the observation and remembrance of unrelated facts, would be extremely small, while its utility as a means of intellectual culture is absolutely nil. It is only when anatomy takes on a synthetic character, and becomes comparative in its method, that it first assumes the quality of a science. Nevertheless, anatomy is indispensable in a medical education, and to be of any service it must be almost exclusively practical. Now, practical anatomy means dissection, and this study is, to a beginner, revolting and disgusting. No man of nice feeling can at first take any pleasure in dissecting a human corpse. To remain unmoved in the presence of death indicates a callous rather than a courageous disposition. I envy not that man who enters a dissecting-room for the first time without an "inward horror." Men who have afterwards become enamoured of anatomy and acquired authority in it have recorded their first repugnance to dissection. Aristotle, the founder of comparative anatomy, and who is said to have dissected as many as five hundred different kinds of animals with his own hands, expresses the repugnance that he felt at the sight of the primordia of the human body. Haller observes that the "nature of death impresses us with horror, and that there is nothing sadder than a deadhouse." George Henry Lewes, distinguished alike as an anatomist,

physiologist, and philosopher, has eloquently described the repugnance which human dissection creates, and the fascination by which it can alone be suppressed. "The fascination must," he says, "be strong, for the disgust is powerful. Our senses are affected by the sickening scent of a corrupting body, by the painful sight of blood-stained instruments, and the scattered shreds of a dismembered corpse. There is also a deeper moral disgust, peculiarly affecting to imaginative minds. The spectacle of death is always accompanied by a certain awe. At the bedside or on the battlefield no gazer remains unmoved; pity, and a sense of community in death, steal over every mind when unshaken by violent emotions. How much more painful the dissecting-room, where the corpse is untended by affection, and unpitied by strangers! none of the sanctity of death surrounds it; none of the tenderness of love watches over it; none of the ceremonials of respect defend it. There it lies, naked, and alien alike from affection and respect, flung upon the table in oblivious disregard of its having once been the temple of a human life. It is no longer that temple; it is not even a corpse; it has become a *subject*. Yet all these sources of repulsion have been, and daily are, overcome. Men sit patiently for many hours, inhaling the nauseous odors, exploring with their scalpel the winding intricacies of vein and nerve, steadfast, patient, victorious. They have suppressed the suggestions of the scene by firmly fixing their minds on the object of their task. It is not because their sensibilities have become obtuse, but because their power of abstraction has overcome the solicitations of suggestion. They have not become hardened; they have simply learned to concentrate their thoughts upon a definite pursuit. Were it not for this we might wonder that men did not consent to remain for ever unenlightened on the marvels of their organization, rather than acquire the knowledge by so repulsive a route." But when the prejudice against anatomy is finally overcome by the passion for knowledge it even intensifies the finer sensibilities of our nature. Bossuet, of whom it has been said, "he is not so much a man as a human nature with the temperance of a saint, the justice of a bishop, the prudence of a doctor, and the might of a great spirit"—Bossuet, with all his delicate and tender sympathies for everything that was pure, noble, and refined, was not repelled from the study of anatomy, and even wrote a tractate upon it; and Goethe, though a practiced anatomist, could not look upon the body of Schiller dead.

While anatomy furnishes the material substratum of physiology, there are other studies equally necessary in the investigation of the phenomena of living matter. Botany and chemistry are only second in importance to anatomy; and though it is the fashion nowadays to decry botany and to advocate its abolition from medical studies, I entertain a very strong opinion that in the whole range of natural science there is no subject so well adapted for initiating a student into the Inductive Method. It encourages observation, it affords the opportunities of generalization, and, at a very small expenditure of time and money, enables the student to gain an insight, pure and experimental, into the operations of living matter. Standing, as it does, midway between the animal and mineral worlds, botany, it has been observed, indicates their relation to each other, and at different points touches the confines of both. It throws great light on the functions of nutrition, and on the laws of development; while from the marked analogy between animals and vegetables, there is every reason to hope that its further progress, assisted by that of

electricity, will prepare the way for a comprehensive theory of life to which the resources of our knowledge are still unequal, but towards which the movements of modern science are manifestly tending. Botany, it is true, may not now be of the same technical value to the practitioner as formerly, but its educational value to the student has correspondingly increased. It will be an evil day for medicine when all its studies are regulated only by considerations of utility. This word "utility" is the bane of modern education. It is tending to eliminate all culture from scientific pursuits. It is an *ignis fatuus* that is leading us into a bog of stolid dullness. Those who cannot see any relation between a liberal education and the requirements of practical life are constantly clamoring for the substitution of technical instruction for classical and literary studies. The pernicious influences of the doctrine of utilitarianism have not, perhaps, made such havoc in England as they have in America, but they threaten sooner or later to confound us. Over fifty years ago Longfellow raised an eloquent protest against the absorbing utilitarianism of the age. "With us," he says, "the spirit of the age is clamorous for utility; for visible, tangible, utility; for bare, brawny, muscular utility. We would be roused to action by the voice of the populace and the sounds of the crowded mart, and not 'lulled asleep in shady idleness with poets' pastimes.' We are swallowed up in schemes for gain, and engrossed in contrivances for bodily enjoyment, . . . as if this particle of dust were immortal, as if the soul needed no aliment, and the mind no raiment." We too often limit the application of the word *utility* to those acquisitions and pursuits which are of immediate and visible profit to ourselves and the community, regarding as comparatively or utterly useless many others which, though more remote in their effects and more imperceptible in their operation, are, notwithstanding, higher in their aim, wider in their influence, more certain in their results, and more intimately connected with the common weal. "The word 'utility,'" continues Longfellow, "has a wider signification than this; it embraces in its proper definition whatever contributes to our happiness, and thus includes many of those arts and sciences, many of those secret studies and solitary avocations, which are generally regarded as useless or as absolutely injurious to society. Not he alone does service to the State whose wisdom guides her councils at home, nor he whose voice asserts her dignity abroad. A thousand little rills springing up in the retired walks of life go to swell the rushing tide of national glory and prosperity; and whoever in the solitude of his chamber, and by even a single effort of his mind, has added to the intellectual pre-eminence of his country, has not lived in vain, nor to himself alone." In the medical profession, the greatest and the best have usually been the most cultured and the least tainted by this spirit of utilitarianism. Hippocrates, Galen, Linacre, Boerhaave, Haller, Mead, Friend, Francis Adams, and Daremberg were all scholars; and even among the men of the greatest practical skill, not a few have been distinguished by their attainments in elegant and polite learning.

As to the way in which you are to pursue your studies, there is little for me to say. Of advice you have no doubt already had as much as you care for, and despite any suggestions or recommendations I might make, you are more likely to fall in with the traditions of the place, and with the practices of your fellows, than with any theories of mine. But take care that the traditions you follow are the best traditions. Do not forget that diligence and industry will make up for many

intellectual imperfections. Remember, too, that your organization is multiplex, and that you need to train your senses, your understanding, and your reason, and have all your faculties under the governance of a resolute and vigorous will. "All our knowledge," says Kant, "starts from the Senses, goes on from them to the Understanding, and ends with Reason, than which nothing higher is found in us, either to work up the material which we derive from the intuitions of sense, or to evolve the highest unity of thought." To be, then, useful and accomplished men, it is necessary for you to engage in those exercises which will train your external senses, cultivate your understanding, and refine and ennoble your reason. The medical curriculum embraces studies adapted to each and all these purposes. What they are and how they are to be pursued, I will not now stop to explain. But a caution is needed. There are two extremes to be avoided; almost equally dangerous, though in different ways—working too much is nearly as bad as working too little; perhaps of the two the more grievous damage is done by excess. An idle and desultory student may, by resolute application, do something to redeem the follies of the past; but a student who, through misguided zeal, or over-anxiety, or from fear, has lavished his strength too prodigally on his task, to the neglect of his physical well-being, may find too late his forces undermined and his energies consumed. Regulate, then, your hours of work, and study so that you may have ample leisure for the needs of recuperation, recreation, and refinement. Learn the secret of losing time rationally. Literature, music, the drama, the fine arts, and the society of persons of refined, though simple, tastes afford abundant opportunities for instruction and amusement and facilities for the best æsthetic culture. Out-door exercises, as walking, boating, cricket, Volunteering—whether you enlist in the service of Mars or in that of Hygeia, to shoulder the rifle or attend the ambulance—will invigorate your body, refresh your mind, and repair the damage your growing frame sustains in the noxious atmosphere of hospital, laboratory, and dissecting-room. These exercises, too, supply the only opportunities of witnessing and admiring the natural beauty of earth and sky and sea; the variegated hues of gem and flower; the painting of insect, bird, and beast; the brightness of sunshine, the iridescence of the rainbow, the rippling of shallow streams, the sheen of still water, the flash and roar of storm and tempest. A memory plenished from the storehouse of poet and philosopher, artist and orator, novelist, historian, and divine; a mind that gives "to forms and images a breath and everlasting motion;" "an eye made quiet by the power of harmony and the deep power of joy" will soothe the tired brain, bring solace to the careworn heart, brace the unstrung nerves, and lighten the weary tread. Cultivate the habit of wishing to discover the Good and the Beautiful in all that meets and surrounds you; the disposition that

"Finds tongues in trees, books in the running brooks,
Sermons in stones, and good in everything."

Gentlemen, no education should be exclusively technical or even intellectual, and certainly not that of a medical man. Hippocrates gave ethical dignity to medical practice. No one showed more respect than he for patients, more solicitude for their welfare, or at least for their solace and consolation. No one has ever had a more correct appreciation of the relations which should exist between medical men themselves and between the medical practitioner and his patient and the public. Guy of Chauliac, who flourished in the middle of the

fourteenth century, was equally exalted in his ideals. "A surgeon," he says, "should be learned, expert, ingenious, and well mannered; he should be bold when sure, cautious in danger; kind to patients, gracious to colleagues, modest in giving an opinion; chaste, sober, pitiful, and merciful, and not greedy of gain." These are noble teachings, which each of us may follow, however haltingly and afar off. Whatever may be our ideals, they have only moral value when they amend our lives. Grave deep upon your hearts the moral maxims of the master mind of medicine, and of the illuminator of modern philosophy. "With purity and with holiness I will pass my life and practice my art" was the pledge demanded by Hippocrates of every novice of medicine; and "Never act otherwise than so that you can will that your maxim should become a universal law" is the unsurpassable ethical dictum of Immanuel Kant. Inexperienced in the course of the world, incapable of being prepared for all its contingencies, ask yourself: Can I will that my principle of action shall be a universal law for the guidance of every other man? Be not deceived; the study and practice of medicine are not of themselves refining or ennobling to the natural man. Among those who are engaged in the treatment of disease are some of the meanest and cruellest of their race. Quacks and pretenders have been the pests of every age. What elevates and ennobles medicine is Science—that "fair, effusive ray" which Akenside, himself a distinguished physician, invoked as the guiding principle of his life.

"That last best effort of thy skill,
To form the life, and rule the will,
Propitious power! impart;
Teach me to cool my passion's fires,
Make me the judge of my desires,
The master of my heart."

"Raise me above the vulgar's breath,
Pursuit of fortune, fear of death,
And all in life that's mean;
Still true to reason be my plan,
Still let my actions speak the man,
Through every various scene."

It is Knowledge that purifies our nature; it is Science that gives moral dignity and value to our calling. To a worldly-minded man the rewards of medical labor are not worth the toil. The remuneration is not adequate to the anxious and arduous care of professional life; to the struggles against opposition, adversity, and disappointment; to the lack of honors, luxuries, and even comforts. But to a mind imbued with the modest and unselfish spirit of science, the rewards of a good conscience and of a sense of duty properly performed, are sufficient. You, and all of us, are engaged in the pursuit of this science, and in a work of humanity and love. We are inheritors of a useful art, the heirs of a noble learning, the depositories of godlike knowledge. On our efforts, collectively and individually, will depend in a large degree the character and the influence of our art and our science during the coming generations. The way in which we discharge our duties and fulfil our obligations to the profession, to ourselves, and to the world, will influence for good or for evil medical and social life for years to come. Higher than mere earthly honors and earthly dignities, the reward we covet is that of being numbered among the true workers in science and searchers after truth—Science that has revealed the mysteries of our organization, eradicated superstition from our minds, extended wide the bounds of knowledge, and put back the limits of the unknown, abridged both space and time, strengthened our intellectual

gaze till we almost pierce the veil of Eternity and realize the Life beyond.

Gentlemen, my task is nearly done. I have only to add my own good wishes to those of my colleagues for your health, happiness, and success.

An Introductory Address

DELIVERED AT

MIDDLESEX HOSPITAL, LONDON,

On Oct. 1st, 1883,

By A. PEARCE GOULD, M.S., F.R.C.S.,

Assistant-Surgeon to the Hospital, and Fellow of University College, London.

GENTLEMEN—With my first word I would, in the name of my colleagues, welcome you, one and all, to-day. Some of you are stepping over the very threshold of that professional life to which you aspire. Others of you have advanced more or less far along its path. But whether here as freshmen, as seniors, or as past students, we are equally glad to meet you, and to wish you well, at this the commencement of another medical year.

Those of you who met here twelve months ago will not have forgotten the sad cloud which then hung over the proceedings, and threw a cold gloom over the opening days of the session. He who was to have addressed you lay dead, called upon, apparently far too soon, to lay aside the toil which had been so pleasant to himself and so beneficial to you. Mr. Lyell had not lived long enough to win for himself loud-tongued popular applause; but here, in his adopted professional home, he had lived so well and worked so earnestly, that he quickly won, and to the last held, a very high place in the esteem of all who knew him. It was never my privilege to know Mr. Lyell intimately, and it would therefore be unbecoming in me to speak of him in anything more than general terms in the presence of many who knew him well and who watched him day by day in his patient labors. You know his sterling uprightness, you have seen his earnestness of purpose, you are witnesses of his ability, and his thorough knowledge of his profession, and many of you have profited largely by his marked success as a teacher. I scarcely need to remind you of these things nor to urge you to cherish and to honor the memory of so good a man. It may well fill us with painful wonder when we have to stand by and to see a life so full of promise so soon cut off, when an abundant seed-time has no harvest, and bright hopes are early blasted. But happy is it when with the feeling of wonderment is blended the grateful recollection of large powers used with a noble unselfishness that withholds not life itself. And such is our memory of Robert Wishart Lyell! Believe me, sirs, the years of such men's lives are weighed, not counted.

By the death of Dr. Alexander Patrick Stewart at the ripe age of seventy, which occurred towards the close of last session, we have lost a member of our consulting staff whose name will never be forgotten while the history of medicine is preserved, and whose memory will always be affectionately cherished by those who were honored with his friendship. It is now seventeen years since he severed his connection with the school and the active duties of the hospital, but to the last he retained a keen interest in both, which he was quick to show when any occasion demanded it. A sketch of his life, could I have drawn it,

might have worthily formed the subject of the address to-day; but that was only to be attempted by one who, from constant association with him, could appreciate his private worth and professional attainments. When but a young man of twenty-seven he wrote a paper, founded upon observations made while he was house-surgeon at the Glasgow Infirmary, whereby he established his claim to rank among the very first physicians of the age. In it he suggested that typhus and typhoid fevers are two distinct affections, unlike in their origin, course, and mode of propagation, and in this he was the first. It is but just to his memory to assert that the service he thus rendered scarcely met with due acknowledgment; but he, happily, sought elsewhere for approval of his actions, and his blameless life secured him that which no popular applause could ever have won for him. Dr. Stewart was a man eminent for his Christian virtues. Possessed of high birth, and a finely cultured mind, he happily combined with these a gentle spirit, and cheerfully accepted as his guide in life the precepts of the New Testament. He was thus enabled to live above the touch of slander, a praise among his friends—of enemies, he had none. In his early devotion to his profession, his careful and accurate observations, and in his Christian integrity and manly defence of all that he held to be true and just, he sets everyone of us a worthy example. And whenever in after life you meet with his name—as often you will—and are reminded of his great work, do not think of him simply as a wise physician, with remarkable insight into disease, but remember him also as a good man. Notwithstanding his professional attainments and charming personal character, Dr. Stewart failed to attain the highest rewards of his profession. And it is well that you should know that this was simply due to habits of unpunctuality, which in him became so exaggerated that it was impossible for him to undertake many of the responsibilities of his calling. This peculiarity he seems to have inherited from his father; but it is very remarkable that one possessed of so much strength of character, so strict in his views of duty, so unflinching in his adhesion to truth, should have been enslaved by a habit that men of far inferior gifts and motives find no difficulty in withstanding. But so it was.

There is one event in medical politics that has occurred during the recent session of Parliament that calls for a brief notice at my hands. A Royal Commission having been appointed to examine into the mode of granting licenses to practice medicine and surgery in the United Kingdom, reported against the system at present existing, and made certain excellent recommendations. A Bill was introduced by the Government embodying these proposals, and was quickly passed through the House of Lords. But the obstructive tactics of individuals and bodies, not wholly disinterested, prevented its being read a second time in the House of Commons. There can, however, be no doubt that the Bill in its main provisions gave intense satisfaction to the general body of the profession, and it is to be hoped that the only result of the tactics of the representatives of the obstructive corporations will be that they will obtain less generous terms when the Bill is next presented to Parliament. These particular corporations have degraded the profession and deceived the public, and are not worthy of the sympathy of either of the parties so deeply interested in this great question. The points dealt with in the Bill on which there is a consensus of opinion are three:—1. That everyone shall be required to pass a final examination in the three branches of medicine, surgery, and midwifery, before being

eligible for registration as a qualified medical practitioner. 2. That this necessary examination shall be conducted by some body other than any of the existing corporations. 3. That the general body of the profession shall be represented on the boards controlling these examinations. Legislation on these lines is urgently needed, and is confidently expected as one of the earliest results of the coming session of Parliament. I hope that he who addresses you next October will be able to refer to it as an accomplished fact, and it may then be his duty to explain to you the effect of the Act upon your studies and your future course.

[Mr. Gould cautioned his hearers against setting too high a value upon success in competitions for prizes, and urged them to try rather to conquer themselves than to over-reach their fellows.]

Not the smallest of the difficulties that beset the introductory lecturer of to-day is the choice of a subject on which to address his audience. There are very few matters in any way connected with the science and art of medicine that have not formed the theme of introductory lectures. History, biography, philosophy, and morals have all been spoken of over and over again; minute directions as to the best mode of study, the medical curriculum, medical examinations, and the preparatory training for the profession, have all been dilated on year by year; and exhortations, warnings, encouragements, and even discouragements have been lavishly given. I feel it impossible to say anything new to you, and not less so for me to put old truths or arguments with as much force as has been done by others, and had I the courage of my convictions I should discharge my obligation to you to-day by reading one of the classical addresses that are admitted to have a permanent value. I propose, however, to refer briefly to some points connected with the manner in which your studies here should be conducted. I offer no apology for this subject. It is important that you should commence your work with an intelligent appreciation of its purpose, and of its method; and as, in the hurry of your student life there is danger that these may be lost sight of, it is well from time to time to have your attention recalled to them. To take up every subject in the curriculum, and to dilate upon its value, and upon the mode of study best adapted to acquaint you with it, would of necessity be very wearisome, and I purpose to deal with two points only—one of them having a special bearing upon the work of freshmen, the other being of interest rather to the seniors.

We are all of us apt to be unduly influenced by the pressing matters of our daily life; and I should not be surprised if some of you therefore regard as the object of your highest ambition the possession of a double diploma in the shortest time allowed by law. It may appear to you that if only you are able to pass your primary examination at the Royal College of Surgeons at the end of your second winter of study, and then to pass the final examinations for the diplomas of member of the College of Surgeons and licentiate of the College of Physicians two years later, you will have good reason for self-gratulation, and that you will never be able to reproach yourselves with having mispent these precious years of your life. But the science and art of medicine is one thing, and the science and art of passing examinations in it quite another. Yet, as the demand for the one is immediate and pressing, it is often difficult to keep the mind always engaged in the higher, grander work of unravelling the secrets, and becoming acquainted with the laws, of Nature.

I know of no reason why I should speak evil to

you of examinations; there is an element of evil in them, as in most things human, and were I so inclined I might seize this, exaggerate it, and, disregarding all their countervailing merits, win the hearty applause of those of you who have not yet finished with them, by assuring you that they are fallacious tests of knowledge, the chief cause and encouragement of faulty modes of study, and, as being both deceitful in their results and encouraging deceit in the candidates, to be avoided and spurned by all honest men. But examinations properly conducted are of the highest value, if the limit of the test they afford be steadily kept in mind. Good as they are, however, the concurrent experience of all candidates is that no examination has yet been devised which is so good as to justify its repetition; and although there are some who linger fondly round examination halls and coquet with their diplomas in strange fashion, they are in the habit of explaining their conduct by the malign action of some ogreish examiner rather than by their high appreciation of the delights of oral examinations. Pass your examinations as quickly as you can; but remember that unless you have far better qualifications for practice than the possession of two parchment rolls you will come short of success both as students and as practitioners. Dismiss from your minds at once all such crude notions as that our work as teachers has no higher aim than to enable you to obtain diplomas in the shortest possible time. Diplomas are but the outward and visible sign of a minimum of inward knowledge and education, and in that they testify to *knowledge* rather than to *understanding* they fail, and always must fail to some extent, in their chief purpose.

It is now generally recognized that the purpose of education—as indeed the word itself denotes—is not so much to store the memory with facts as to develop and train all the mental faculties, of which memory is but one. The study of medicine and the sciences upon which it rests is eminently adapted to render this training of your natures complete. Your work will educate many of your bodily powers to a high degree. The practical study of anatomy, of histology, and of ophthalmology will train your eye; the careful practice of stethoscopy will develop your ear; and how can you better train your muscular sense than by dissecting or operating, or by acquiring that gentle strength so valuable in such manipulations as the setting of fractures? You will, however, need to supplement this by some athletic exercise; which should be more vigorous than the act of drawing a pipe, and taken in air clearer and purer than is to be found in a public billiard room. In regard to your mental faculties, it is the case that few pursuits are better adapted for training the memory than are anatomy and *materia medica*. The faculty of observation may be cultivated to its highest pitch by dissection, botany, histology, and the clinical observation of disease. You will find that the development of your powers of imagination is amply secured by a credence of therapeutical records, and the problems of diagnosis will train your judgment as few other pursuits can. Nor is the moral side of your nature uncared for. No thoughtful man can witness unmoved the unrelenting course of Nature, or her wonderful adaptation of means to ends, her patience, or her mystery. To be brought into contact with all classes of your fellow men, under all the varying conditions of pain and disappointment that form so great a share in the lot of everyone of us; to have the responsibility of life and death resting with you, and to be the depository of secrets more sacred than those of priest—for while his refer only to the hidden past, yours often reach on into the veiled future, and enable

you to foretell the slow but certain march of events unborn—these things, with many other incidents of your daily life, are fitted to raise you above the level of our common fallen humanity, and to cleanse the inner currents of your life.

You will believe me when I say that your first aim should be to understand the body in health. The processes and conditions of disease are but modifications of those of health, even although their causes may, in some instances, be organized bodies introduced from without, and the events in their life history. Nor is there a sharp boundary line, on the one side of which is health, and on the other disease; the one state passes by imperceptible gradations into the other. We speak of a standard of health, but it is easier for physiologists to define than for physicians to recognize; and while we can formulate in our minds the earliest steps in morbid processes, they are so minute that we can only observe them in the mass. It is like the growth of the individual. We can define an infant, a boy, a youth, a man, and an old man. We can recognize at a glance well-marked examples of each class, but the progress from one stage to another is so gradual that it is impossible to state precisely where the infant becomes the boy, the boy becomes the youth, the youth the man, and the man becomes senile.

Much of your work in the future will consist in preventing and treating affections which, so far as we know at present, originate in trifling and imperceptible disturbances of the processes of health, and which, allowed to go on unchecked, culminate at length in obvious disease. The *anæmia* met with so often in the inhabitants of large towns, the combined result of bad air, deficient sunlight, unsuitable food, injurious habits of various kinds, overwork and worry, is a case in point. Nor could I choose a better example than is afforded by chronic alcoholism, the sum of the effects of a long-continued indulgence to excess in alcohol. Your first two years will be devoted almost exclusively to the study of the body in the condition of health, and inasmuch as the knowledge then gained is the foundation on which all that follows after must rest, and sets limits to it, and as in those years habits of study, good or bad (to say nothing of habits of life), will be formed by everyone of you, which will help or hinder you in all your subsequent career, you cannot be too intent upon setting out upon the right road under wise guides. This study you will carry on in the classes of anatomy including histology, and physiology including all that part of chemistry which refers to the tissue-changes of the body. Anatomy deals simply with the structure of the body, the form, relations, connections, and consistence of its various component parts; it is a study of physical characters only, and can therefore be conducted on the body after death. Physiology, on the other hand, has nothing to say to structure as a physical phenomenon, but deals with the function, the use of every part, explains the "why" and "wherefore" of every physical feature, and is an exposition of all by which a body during life is distinguished from the same body after death. The wide extent of each of these studies necessitates their being taught in separate classes; but the severance thus made—partial though it be, and of quite recent growth—has rather tended to obscure the essential unity and interdependence of the two sciences. Of late we have heard eloquent dissertations on the *relative* value of these twin sisters, which is as well worthy of discussion as is the relative value of maiden beauty and the power of vision to discern it. The relation between structure and function is a problem of the greatest in-

terest, and the degree in which each is dependent upon the other is by no means a settled point. Viewed historically, anatomy certainly precedes physiology, and the starting-point of physiological science—the discovery of the circulation of the blood—rested chiefly upon anatomical observations. The growth of physiology was coincident with a more detailed study of anatomy; then came the microscope, with its wonderful revelations of intimate structure, and, again, physiology expanded; and this aspect of the science having been fully developed, she is now busying herself with the forces of life itself. So, gentlemen, must it be with you; proceed from anatomy to physiology. If you would learn either well—and this is what I want chiefly to impress upon those who are commencing their medical studies—you must disregard the fact that these two sciences are taught by two lecturers, and view them as one and inseparable. Structure without function is death, and you are here to study life. Function apart from structure is impossible. Unless you study anatomy from the physiological standpoint, you will at best be ignorant of the living body, and blind to the charm that is associated with every scientific pursuit when properly conducted. The mind soon wearies under a load of disconnected facts, but the powers of observation never tire when their acquirements are assimilated by those of the imagination, and association has ever been found to be the chief aid to memory. If therefore you would learn anatomy easily and pleasantly, and would remember it without difficulty, you must search for the physiological equivalent of every anatomical fact. Never be content with any observation until you have grasped the association it has with other facts, and its influence upon the function of the part. To know that the artery of the arm courses along the front of the elbow, while that of the thigh runs along the back of the knee, is to you of small value until you realize the reason for the arrangement, and notice the ill effects that would follow the movements of the joints were the conditions different.

Gentlemen, all this must appear very self-evident to you. But I offer no apology for referring to it, for I have seen only too often the neglect of this truth and practice lead to the shipwreck of the student. It would be no great exaggeration to say that it is the exception rather than the rule for students to study anatomy with what I will call physiological eyes and minds. In place of that they regard it as a dull exercise of memory; the mere addition of fact to fact soon loses all interest to them, and they either lay aside the unwelcome task and abandon themselves to other pursuits not included in their curriculum, or they plod on wearily in their useless work of piling up lifeless "fact-heaps." This is no fancy of mine. The great danger that imperils every one as he enters upon the study of medicine is an unintelligent mode of study; only set out upon your course along the right path, aided by the helps that lie ready to your hand, and you will be safe from the snares and pitfalls that have entrapped the feet of many of your fellows. If you thus study anatomy, not only will you acquire a true scientific knowledge of it, but you will form a habit of thought which will be of the greatest value to you in all your other medical pursuits. What I have said in reference to anatomy applies with equal force to physiology, pathology, medicine, surgery, chemistry, or therapeutics. For example, influenced by this habit of mind, you will not be content to learn simply the mere phenomena of life as described to you by physiologists, but you will push your inquiries into their causes and results, their influence upon each other, and the

consequences of their modification. Thus, to be told that the normal frequency of the pulse is seventy-two beats a minute will only prompt you to inquire why it is of this frequency, how this rapidity is maintained, how it may be modified, and what effects such modifications have upon all the parts and functions of the vascular system. Similarly, you will supplement a knowledge of the fact that the temperature of the body is kept at one uniform level independently of the temperature of the surrounding medium, by inquiries as to how this is secured, and into the causes and consequences of its variation. And so he who converts the science of anatomy into a department of physiology will elevate the study of physiology from a survey of the phenomena into an unravelling of the processes of Life. By working thus you will not only train your minds while you are gaining an intelligent—albeit imperfect—knowledge of the living body in health; but the acquisition of a sound knowledge of disease, and insight into its treatment, will be robbed of its chief difficulties. While your faculties of observation, sharpened by daily use, will quickly make you familiar with the commoner and more important features of the disease, your physiological knowledge and instinct will enable you to assign them to their true causes, and to determine the lines along which your efforts at treatment must be planned. You will see in your patients a series of unwilling physiological experiments of endless variety. You will be struck with the fact that in leaving the laboratory for the wards you have not entered upon a new departure in your work, but that health and disease are but manifestations of the reign of the same laws under different conditions. Indeed, if physiology be understood as the science of Life, then all your studies here will be physiological, and should be continuous, as the subdivisions of one great whole.

The same state of mind is just as essential in the study and practice of therapeutics; the difficulties that beset you there are so great that it requires the utmost vigilance to escape from the domination of "rule of thumb" which satisfies too many among us. Your chief safeguard against this danger will be the early formation of the scientific habit, which becoming a second nature, will render the practice of empiricism almost impossible. Surgical therapeutics, as more scientific and better understood than the uncertain treatment of the physician, will present to you the greater attractions; but each should command your approval only as it can be shown to be in conformity with established physiological laws.

We have lately seen great advances made in the localization and the precise diagnosis of disease. No one can doubt that this has been of great advantage. But, as students, let me caution you against giving your attention too exclusively to this side of disease, to the neglect of its more general aspects. Remember that you always have in your patient, not a disease so much as a disturbance of the workings of that complex machine whose mechanism you become familiar with in the earlier part of your course. You won't understand me to minimize the importance and value of precise diagnosis, but let not precision in one detail or in one direction be associated with carelessness in and neglect of others. It is quite possible to define with the greatest nicety the extent of consolidation of a lung, and yet fail to distinguish between a case of pneumonia that will quickly end in death and one that will as quickly be recovered from. The best example I can give you, however, is that of fever. The condition of fever is met with in association with very varied states, and

the distinctions between different fevers are points to which you will of necessity have to devote much careful attention. But beware lest your desire to be able to distinguish accurately and readily the different febrile diseases from each other lead you to neglect the most careful study of that element which is common to them all—the fever. Among local conditions inflammation affords me a parallel example. Occurring in all tissues, and in many varieties of intensity, with associations the most diverse, it yet is one and the same nutritive disturbance in every case. And therefore, while endeavoring to distinguish different inflammations, don't lose sight of the great uniformity of the process, wherever existing. Degenerations, hypertrophy, tumour formation, and the effects of irritation, are all other examples which I could have used to illustrate the importance of general pathology. Pathology is primarily and mainly general. When you remember that the chief factors in morbid processes—the influence of the nervous system and the circulating fluid—are the same in all tissues and organs, and the intimate processes of nutrition, if not identical, are so closely similar as to be governed by the same general laws, and influenced alike by the same conditions, you will be prepared to find a uniformity in disease as it affects different parts of the human frame. Every local change is a study in general morbid processes, and you will notice that the fact of locality has far more influence upon the effects of disease than upon disease itself. For instance, a cancerous tumour, occurring where it will, affords you a picture not simply or chiefly of a tumour of one special part, but far more strikingly of a particular variety of morbid growth in general; and the knowledge you may gain of its life-history as observed in one region is applicable to a similar growth wherever met with. The importance to the patient of whether the cancer be in the lip or the liver is no doubt vast, but is due to considerations quite other than the nature of the disease from which he suffers.

Take the case of wounds also, and by wounds I mean, of course, all breaches in the continuity of tissues; the modes in which they are produced are but little modified by locality. But of greater interest is it to notice that the healing process is, with insignificant exceptions in matters of minute detail, identically the same in all wounds, whether cutaneous or subcutaneous, whether implicating skin or muscle, or bone or brain; the recognition of this fact simplifies your task as students very greatly. What you see in the healing of a harelip is just what takes place hidden from your view—when a tendon is divided subcutaneously, or in the repair of a well-set fracture; and the healing of an ulcer in the skin is a picture of the re-formation of a bone after its death and removal by the surgeon. The healing process is not only identically the same in all cases—for it consists essentially in the effusion and subsequent organization of coagulable lymph—but the conditions which modify this process, such as position, movement, blood-supply, irritation, and the like, have precisely the same influence upon it in all situations. Thus, it does not require a broken bone to illustrate the causes of non-union of a fracture; a harelip will serve equally well; and from the study of a cut finger we may learn to carry out the treatment of the largest amputation wound.

This fact is not without importance to you. It should add to the interest and zeal with which any case is observed and studied, to reflect that from it lessons can be learnt of general, or even universal, application; the experience gained from any case should extend far beyond that

particular example of disease. It is only as you bear this in mind that you can become in any way qualified for practice by the brief term of study demanded by the curriculum. In four short years you cannot become familiar with disease in all its phases, and with every variety of injury. But you can by diligence, and by patient observation, acquire a knowledge of all varieties of morbid processes, and of physiological therapeutics. As new cases of diseases come under your care you will then be able to unravel and treat them by the application of this knowledge.

But if this be true, it also has some bearing upon the latest fashion in the profession—that of specialism. There is a spirit of evil abroad that would map out the body into cubic inches, and place each segment in the care of a "special" medical attendant. Each of the natural orifices of the body already has its swarm of "specialists," who buzz about it like some cloud of pestilential flies; and attempts are being made to place every artificial orifice under similar false protection, and to hand over the performance of each single operation to those "specially" devoting themselves to its performance. A certain kind of "specialism" is an unmixer good, and a necessary result of the variations in our lot in life, and in our individual tastes. I need not define this accurately to you. In our hospital staff alone there are several distinguished men, who have added to a wide knowledge and ripe experience of the general domain of medicine or of surgery a special acquaintance with the diseases of particular parts. The department of ophthalmic medicine and surgery has always been distinguished by being largely in the hands of general surgeons, and both it and surgery as a whole have greatly profited thereby. And just in proportion as it slips away from the hands of general surgeons into those of men whose purview is limited to the tiny orbs of vision will it be in danger of falling from its present high position.

But of the common form of "specialism," which may not improperly be called a disgrace of our time, I should be ashamed, in this public place, to tell "the truth, the whole truth, and nothing but the truth." If, however, you are seeking for ignorance of the science they profess, for the dishonest arts which degrade a noble profession to the level of a huckstering trade, it is to the consulting rooms of some of these "specialists" that you must go. Some of the fraternity have one good claim to be called "local specialists," in that they are entirely ignorant of every thing that is outside the small portion of the human frame they have chosen to take under their special care. But lest I should be tempted to speak evil of some of my professional brethren I will not further characterize them. One or two of the evil results of "specialism," however, it will be well for you to be on your guard against. The first of these is the tendency to multiply operative methods of treatment. While not saying that these operative measures are, all of them, or of necessity, bad, yet I believe the measure to which a practitioner resorts to them is a very fair working test as to his position in the descending scale of "specialism." A second result, closely connected with the first, is a tendency to complicate these said operations, to invent elaborate instruments, and to make small and unnecessary modifications in recognized proceedings, so that the individual's practice becomes "special" to himself at the same time that it is limited to one narrow region. In this way a clever "specialist" (of the bad order)—who will, of course, have started a hospital of his own—quickly differentiates his practice completely from that of his better-informed fellows. We won't fol-

low him further. But the result which tells most disastrously upon medical students is the fact that as soon as the diseases of any part are relegated to a "special" department, the study of them is neglected by the general body of students. It thus happens that when they leave their hospital, students are, as a rule, less well-informed in regard to the diseases of the eye, ear, throat, and nose than of any of the maladies which are treated by general physicians and surgeons. This again tends to throw the treatment of such cases into the hands of the "specialist," and a vicious circle is produced. We are bidden, however, to look at the great gains that have resulted from the concentration of experience and observation in certain "special" directions. The fact of the advance is incontestible, but by whom has it been made? The valuable aid afforded by examination of the eye, in cases of diseases of the brain, has resulted from the labors of physicians, not of "pure" ophthalmologists. The modification in the operation of lithotomy, which has reduced its mortality by more than one-half, while extending its range, and which has secured it a permanent place in surgery, was made not by "specialists," who perhaps could count their operations by scores, or even hundreds, but by a general surgeon, whose experience, as measured numerically, was small. I believe that an impartial study of the operation of ovariectomy would show the same fact—viz., that the improvements in the operation which have won for it so high a place in surgery have not been evolved by specialists out of their experience in that operation, but have been the result of the application of general surgical principles, worked out by general surgeons, to this particular case. But I do not make any assertion as regards ovariectomy, lest it should lead to discussion, and a perusal of our medical periodical literature of quite recent times will show you that such discussions are prone to degenerate into unintelligent displays of bad temper.

An examination of the causes of "specialism" would lead me too far; but accept my assurance that none of them apply to you as students, and that the idea of "specialism" should never be for a moment entertained by you. And let me again beg of you not to be ensnared by its existence to neglect the study of any part of the body or of its affections, and to avail yourselves of every opportunity of becoming familiar at least with the apparatus used for the diagnosis of the so-called "special" diseases.

And now, gentlemen, it only remains for me to ask you to give yourselves to your work in no half-hearted way. The task before you is no easy one, and it demands and deserves your best energies. The most richly gifted among you will find in it full scope for all his powers; the most humbly endowed may, by patient perseverance and diligent waiting on Nature, learn some of her secrets, and aid her in her task of healing. Your time is short; the graver responsibilities of life will soon be upon the youngest of you, and you must be up and doing if you would not be distanced in your race with Time. You are here to study Nature; take her not alone for your theme, but also for your pattern. You will find her painstaking, persevering, never disheartened by obstacles, full of resource, patiently carrying out her designs through long years or even centuries. Copy her in these things. You will also find that however secret her plans may be, when they are discovered and brought to light they are such as only to excite our admiration as worthy of a God. Imitate her in this, too, and the pure in heart shall see God.

Original Papers.

A CLINICAL AND PATHOLOGICAL STUDY OF LARYNGEAL PHTHISIS.

By GORDON HOLMES, M.D.,

Physician to the Municipal Throat and Ear Infirmary.

History.—Disregarding descriptions of and allusions to throat maladies by ancient and mediæval writers,¹ who doubtless in some instances refer, though indiscriminately, to laryngeal phthisis, we find that the existence of a laryngitis peculiar to phthisis was adumbrated by Morgagni² in 1764, advocated inconclusively during the succeeding half century by Petit,³ Sauvée,⁴ and others, but first clearly insisted on by Louis⁵ in 1825. The latter author, indeed, remarked, that "ulcerations of the larynx, and especially those of the trachea and epiglottis, must be considered as lesions proper to phthisis."⁶

The dictum of Louis, however, being too indefinite, caused most observers of this period to confound all ulcerations of the windpipe under the name of laryngeal phthisis. To terminate this state of confusion, which was more than suspected by certain of the more acute pathologists, notably Trousseau and Belloc, the Academy of Medicine of Paris intervened in 1836, by proposing the "History of Laryngeal Phthisis" as the subject for a prize essay. Upon this the matter was taken up vigorously by Trousseau and Belloc,⁷ who, working conjointly, gained the prize, and proved indisputably by their researches the existence of three kinds of ulcerations in the larynx—viz., phthisical, syphilitic, and cancerous.

The knot being thus far unravelled a new question for elucidation immediately presented itself—i.e., as to whether tubercle is actually deposited in the laryngeal structures. Louis, in fact, had expressly stated that he could find none, whilst Trousseau and Belloc mainly relied on the argument of analogy from the well recognized tubercular invasions of the intestines to prove the similar liability of the larynx;⁸ but they simultaneously confessed that they had never seen any tubercular matter in the latter situation. Subsequent investigations of French pathologists coincided with this view, and the most weighty authorities—such as Andral,⁹ Monneret and Fleury,¹⁰ and Cruveilhier¹¹—concurred in denying positively

the presence of true tubercles in the larynx. Against this statement Barth¹² and Lheritier,¹³ almost alone in their opposition, aver that they have seen unmistakable tubercle in that organ.

During this phase of the debate the German investigators are first heard in the discussion, and under the leadership of Rokitsansky,¹⁴ Günsberg,¹⁵ Tobold,¹⁶ and many others, affirm the existence of actual laryngeal tubercle. Amongst these the voice of Rühle¹⁷ alone is raised in dissonance to contest such a conclusion and uphold the doctrines of French pathology. At this juncture Virchow¹⁸ enters on the scene with a solution calculated to reconcile the adverse parties and rescue the subject from the field of controversy. This chief of pathologists explains in brief that most observers were accustomed to recognize tubercle only in its advanced or caseous form, whereas that "when miliary corpuscles are found in a membrane exposed to external injury they disaggregate, produce ulceration, simple and superficial, but do not become caseous or give rise to any tumour. To this class," he continues, "belong the tubercles of the larynx which give rise to laryngeal phthisis. . . . The larynx is recommended to those who wish to know true tubercle." And farther, he states,¹⁹ "I am absolutely convinced that laryngeal phthisis is due to tuberculization of the larynx; this conviction is based on thousands of observations."

Nevertheless there is still a band of inquirers in active contention over this disease; and we find those who argue that deposit of tubercle is the primary and continuous cause of laryngeal phthisis, and those who oppose this view with the assertion that it originates in some common inflammatory lesion. For the former body Heintze²⁰ is the chief exponent when he exclaims: "Ulceration of the larynx and trachea without simultaneous or subsequent tubercle of the mucous membrane never leads to laryngeal phthisis." And as a prominent partisan of those biased in the other direction, Lefferts²¹ may be selected from his statement: "Ample authority can be brought to substantiate the assertion that the disease is but a chronic ulcerative laryngitis existing in a consumptive patient, and modified in its course and results by the tubercular diathesis." But between the conflicting ranks the main body of laryngologists proceed inattentive to dialects, and engaged only with the clinical demands of the malady.

Semeiology.—Considered *subjectively* patients affected with throat consumption make the complaints inseparable from any condition of cachexia, such as loss of strength, appetite, etc., combined with such special troubles as direct the observer's attention to the state of the throat internally. Of varied prominence these latter are alteration of voice, dysphagia, pain locally, cough, and dyspnoea.

(a) The invariable first symptom is probably alteration of voice, progressing from a mere necessity for increased effort in producing the laryngeal

⁶ A traditional error has crept into some of our text-books respecting the views of Lennec on laryngeal phthisis. Ziemssen (*Cyclopædia of Medicine*, vol. vii., p. 834) has the following sentence: "As is well known, Laennec's teaching of the purely tubercular nature of laryngeal phthisis early met with opposition. Omitting the word 'laryngeal,' this statement would be correct. Laennec does not even mention laryngeal phthisis in his *magnus opus* (*Traité de l'Auscultation médiate*, etc., Paris, 1826), nor does he refer to it in any desultory paper.

tones, through varying degrees of hoarseness, to complete aphonia²²—i.e., extinction of sonorous articulation. The vocal troubles do not, however, bear a constant relationship to the structural alterations in the larynx, for, as Gerhardt²³ has pointed out, pressure on the right recurrent nerve as it passes through the thickened pleura of a tubercular lung may cause paralysis of the corresponding vocal band with a decided dysphonia, whilst in the case of females a slight congestion of the larynx will often produce aphonia of a character chiefly functional. The interference with speech is usually the immediate cause of the patients applying for medical relief.

(b) At a later stage difficulty of swallowing is likely to present itself; but not without exceptions, and the malady sometimes attains a fatal termination without this symptom. Dysphagia, however, being once felt mostly advances until great pain in deglutition provokes frequent regurgitation of food, and almost prevents the performance of the act. In the worst cases the pain is described as being of an intensely burning character, as agonizing as an actual cautery, and remaining for some time after the throat returns to rest.

(c) In addition to the pain of swallowing there is always more or less tenderness of the larynx on pressure from without, as can be ascertained by grasping the thyroid cartilage between the forefinger and thumb, so as to approximate the cornua. This sign is present at a very early stage, and sometimes seems to precede all others. Nevertheless, pain when the larynx is quiescent is rarely present; a fact "the more remarkable," as Andral observes,²⁴ "because the larynx in health is the seat of an exquisite sensibility."

(d) With respect to cough, this symptom is more allied to whatever pulmonary lesions may exist than to those of the larynx. Great destruction of the laryngeal substance may take place, and cough be altogether absent. Should the lung affection be in abeyance, cough will commonly be so likewise. This fact is well illustrated in a case recorded by Krishaber,²⁵ in which ulcerative ravages proceeded in the larynx for five months without cough, whilst the lungs were not appreciably invaded. Subsequently, however, cough became a prominent symptom simultaneously with the chest lesions markedly declaring themselves. Cough in conjunction with laryngeal phthisis has the peculiarity designated by Trousseau and Belloc²⁶ as "eructant cough," from its similarity to eructation. This phenomenon is due to inability to close the epiglottis, and sounds like blowing through an open tube to expel the mucus. It much resembles the expectorative efforts through the cannula of patients on whom tracheotomy has been performed.

(e) Finally dyspnoea may be noticed as a subjective symptom. In most cases this complication does not originate in the larynx, because a pronounced narrowing of the glottis but rarely arises in the course of the malady. Like cough, therefore, dyspnoea must be relegated to the troubles more intimately dependent on chest lesions.

²² It is worthy of remark that aphonia, though meaning literally "no sound" and primitively speechlessness, is now practically applied to those who can speak only in a whisper. Thus Hippocrates remarks: "ἦν μεθ' αὐτὸν ἐξαίφνης ἀφωνος τις γένηται, σταθεὶς ἀποθνήσκει." *Observationes*, lib. 14, Schol. 33.

The objective study of laryngeal phthisis having now to be considered, the general appearance of the patient will often be noticed as very suggestive of consumption. As he enters the practitioner's consulting-room his stooping attitude, his gait indicative of muscular enfeeblement, and the peculiar pallor of his countenance, are usually an instant revelation of the nature of the case, which is often further assured by the first tone of the patient's voice.

The laryngoscope being then called into use will complete the picture of disease, as far as can be seen in the living subject. The appearance of the larynx differs not only according to the stage of the malady, but also with respect to its form. Two varieties of laryngeal phthisis are practically familiar to all workers with the laryngoscope.

1. The first presents itself as a congestion of the mucous membrane of the larynx, scarcely differing perceptibly from a case of subacute catarrh. It is, in fact, generally set down as such until its persistence and progress to considerable thickening, chiefly of the interarytenoid fold, together with the development of the tubercular cachexia, guide the observer to diagnose phthisis. In the beginning of this form the lung symptoms are always least appreciable, sometimes indeed difficult to be recognized with certainty. Many authorities, therefore, agree in calling it *primitive*.²⁷

2. The second variety, less frequent, appears in many respects an antithesis to the first. It is denoted by a well marked anæmia of the larynx, succeeded in a few weeks, perhaps months, by a remarkable swelling of the tissues covering the cartilages of Wrisberg, and the arytenoid cartilages and of the interarytenoid fold. This tumefaction has a peculiar pale, smooth, and somewhat glistening appearance, suggestive of a passive œdema. It produces those pyriform swellings of the margin of the larynx, diminishing in extent from the arytenoid cartilages towards the epiglottis, sometimes unilateral, but mostly symmetrical, noticed by Mackenzie²⁸ and others as pathognomonic of laryngeal phthisis. Although this kind of tumour never exhibits a uniform congestion, it often shows hyperæmia of the inner parts in the form of a capillary injection or a punctiform redness. It may, however, be accompanied by congestion of other portions of the larynx. These are the cases corresponding to the "tubercular infiltration" of some laryngologists, and as the chest lesions are usually in an advanced state they are most patently consecutive.²⁹

Whatever differences may be perceived in cases of laryngeal phthisis at the advent of the disease, in its later stages the condition is alike one of progressive ulceration. The ulcers, having once begun their task of destruction, almost invariably advance without cessation, and consume the tissues of the larynx by superficial and deep extension. Their floor is usually covered with an unhealthy pus, often streaked with blood, whilst their edges are irregular and frequently show an inflamed areola. At first, however, small ulcers of a lenticular shape are commonly observed, but these by their coalescence soon give rise to larger patches, which may present signs of their origin in having a festooned border. The ulceration attacks with nearly equal frequency the arytenoid cartilages, the ventricular bands, and the epiglottis. Türk,³⁰ indeed, considers that the first ulcers

²⁷ See Krishaber, op. cit., p. 660, Bœckel, Dictionnaire de Médecine et de Chirurgie Pratiques, t. xx., Paris, 1875, p. 258.

²⁹ See Bœckel, op. cit., Krishaber, op. cit.

³⁰ Klinik der Krankheiten des Kehlkopfes, Wein, 1866, p. 374, Taf. xvii., etc.

are situated on the posterior laryngeal wall, at the lower part of the interarytenoid fold, but under these circumstances it is very difficult to see them with the laryngoscope. The vocal bands participate early, and invariably in the morbid process, and become congested, swollen, and marked by small pink granulations; but ulcers, though always present, especially at the posterior part of the opposite edges, in the vicinity of the vocal processes, are scarcely so rapid and destructive as in the other localities.

Laryngoscopic inspection will generally reveal the cause of such subjective symptoms as emanate from the larynx. Difficulty in swallowing may thus be traced to swelling of the arytenoid cartilages and epiglottis, impeding the closure of that valve, and also, probably to stiffening of the perilaryngeal structures, by tumefaction, or otherwise, hindering the necessary raising of the larynx by the elevators of that organ in the act of deglutition. On the other hand, pain in swallowing is indicated visibly by ulceration of the epiglottis, chiefly at the margins, and often by ulceration of the arytenoid cartilages, so disposed as to be brushed by the bolus of food in its descent. Entry of food into the larynx can be explained by imperfect closure of the organ by the epiglottis or the ventricular bands through hampered action or loss of substance of those parts. Interferences with phonation will be found to result from fixity of the vocal bands, caused by swelling of the adjacent tissues, by immobility of the crico-arytenoid joints, by actual paralysis of their motor nerves, or by mere muscular paresis. But in advanced stages, when the vocal bands are almost completely eaten away, the patient may produce crude vocal sounds in various peculiar and abnormal ways, such as by approximation of the ventricular bands, or even, as in a case noticed by Krishaber,²¹ through a kind of glottis arising from an unnatural proximity of the epiglottis and arytenoid cartilages.

As regards expectoration, the bulk of it is furnished by the respiratory tract below the larynx. That which comes from the latter organ is peculiar in often containing fragments of ossified and necrosed cartilages; also straight elastic fibres which Rühle,²² in contradistinction to the looped fibres of pulmonary sputa in phthisis, thinks can be recognized microscopically as proceeding from the vocal bands. Hunter²³ once saw the entire cricoid cartilage rejected. It is not uncommon for the larynx to be almost filled with frothy mucus, which renders laryngoscopic observation almost impracticable.

Pathogenesis.—As all questions relating to the origin of tuberculosis have been reopened by Koch's discovery of the tubercle bacillus, so the etiology of laryngeal phthisis must, in some points at least, be reconsidered in the presence of the new light. Leaving out of sight, however, the great problem as to how the constitution becomes tubercular, it is evident that former observations as to the subsequent progress of the malady may not demand an entire readjustment.

One of the most indeterminate points of inquiry respecting throat consumption is whether the larynx is ever affected before the lungs have been actually attacked. The most acute observers in this field maintain that no laryngeal phthisis ever exists until after the lungs are invaded. The delicacy of the question may be estimated by instancing Ziemssen,²⁴ who, in trying to hold this ground,

appeals to the sign notified by Seitz as to the comparative height of the lungs: if one is found to be more depressed than the other at its apex, it is decided to give evidence of tubercular cicatrization. Yet some good authorities, such as Förster,²⁵ believe in a primary laryngeal tubercle.

Now, although the laryngeal lesions in an advanced state are never dissociated from pulmonary phthisis, yet it is certain that the disease may be very evident in the larynx whilst lung symptoms are almost inappreciable. And on this account formerly arose the question answered in the affirmative, though hesitatingly, by Cruveilhier²⁶—i.e., whether a simple chronic laryngitis could, by developing into laryngeal phthisis, lead to pulmonary consumption. But to this proposition a direct negative can now be returned, as, in the absence of any specificity, no tuberculosis could be established. At the same time it may be logically assumed that such a sequence could occur, not merely in semblance, but in a practical sense. For, by the presence of a simple chronic laryngitis the larynx might become a *locus minoris resistentiæ*, and hence, whilst being initially obnoxious to phthisis, be the point of first outbreak, either through increased liability to direct inoculation or general infection by the bacillus. In conjunction with this theory, however, the question as to the necessity for a constitutional bias or receptivity would have to be considered.

A further point for discussion concerns the morbid action of the sputa ejected from the diseased lungs.⁴ Most early authorities, beginning, it appears, with Sylvius, have argued that phthisical expectoration has an infective or corrosive quality. Amongst them we find Louis,⁵ Trousseau and Belloc,⁶ etc., who are inclined to recognize here the exciting cause of many, if not all, cases of laryngeal phthisis. So far, however, we have no conclusive evidence on this point, but Ziemssen⁷ believes the shallow, extensive ulcers, or rather erosions, of the windpipe so commonly seen at the autopsy in this disease own such an origin. Assuming slight excoriations of the larynx and trachea to exist, through the presence of simple catarrh provoked by cold or the irritating influence of a hacking cough, it has yet to be ascertained that the bacillus, being thus inoculated, would produce *in loco* a fresh deposit tubercle.

The proportion of cases of laryngeal phthisis met with amongst those of pulmonary consumption is shown by the statistics of Willigk,⁸ founded on 1317 cases, as 18 per cent.; by those of Heinze⁹ drawn from 1226 instances, as 30·6 per cent. Statistics given, however, by Mackenzie¹⁰ and Ormerod¹¹ based in each instance, on 100 cases, prove that, if slight morbid changes in the larynx are included, only about 25 per cent. of cases of lung tuberculosis can be pronounced free from laryngeal disease. It is left for the future to determine whether any uniform relations exist between the disease in the larynx and that in the lungs, as to the stage of the latter, and also as to its course, whether rapid or slow.

Sex and age are to be accounted as sources of

predisposition to laryngeal phthisis. How far they are so effective is illustrated by the annexed table of 227 cases treated by the writer:—

Age.	Males.	Percent.	Females.	Percent.	Total.	Per cent
15 to 20	8	3.5	6	2.7	14	6.2
20 " 30	67	29.5	32	14.1	99	43.6
30 " 40	52	22.9	25	11.0	77	34.0
40 " 50	19	8.4	6	2.7	25	11.1
50 " 60	9	4.0	3	1.3	12	5.3
	155	68.3	72	31.8	227	100.2

These statistics show no marked divergence from similar calculations by other observers, but a few cases under ten years and over sixty have been met with by Mackenzie, Heinze, and others.

No decided predisposing influence with respect to laryngeal phthisis has been traced to occupation. There is, perhaps, some slight evidence that sedentary indoor employments favor the development of the disease.

Pathological Anatomy.—It is represented by Krishaber¹² that in the early or catarrhal stages the lesions are more serious than could be supposed from mere laryngoscopic observation. Rindfleisch¹³ has shown that in ordinary catarrh the mucous secretions make their way through the epithelium without destroying it, and Förster¹⁴ has carried the investigation further by proving that even in purulent catarrh the mucous membrane loses very little of its epithelium. But in laryngeal phthisis the epithelium desquamates at a very early period, and a purulent exudation is quickly established from the denuded surface.

The ulcers in laryngeal phthisis are found to have different modes of origin, and hence to exhibit several distinct forms. For, in addition to those pathognomonic ulcers arising from deposit of tubercle, three other kinds have been distinguished by various observers. These latter, though not indubitably peculiar to phthisis, have nevertheless characteristics which are apparent only when they are associated with that disease.

(a) The tubercles of the larynx have the intimate constitution of those found elsewhere. Their progress is best described by Fränkel,¹⁵ the most recent observer. They are first deposited in the mucous membrane beneath the epithelium, and then by the rapid destruction of isolated or conglomerate masses of tubercle a superficial ulcer is formed, which spreads more on the surface than by penetration. The border of the ulcers is round and shows an inflamed area, and their floor is caseous and covered with detritus. Tubercles are also deposited in the walls of the ulcers; indeed, as Heinze¹⁶ shows, their whole superficies may consist of a layer of tubercle. The tubercles are well supplied with myeloid cells, and appear to affect by preference the lymphatic tissue of Coyne.¹⁷ Heinze¹⁸ alone finds that, besides the fresh tubercles, there are others of "old date, with slight beginning of fatty metamorphosis or such marked caseation that only a small ring of the original form is seen."¹⁹ According to the same authority, when the mucous membrane is infiltrated with tubercle it is thickened three or four-fold, and he describes the state of the bloodvessels²⁰ in the

masses of tubercle. Thus the walls of the veins are entirely replaced by tubercle, whilst the adventitia and intima coats of the arteries succumb in the same manner, but the muscular tunic exists through all comparatively intact. In fact the muscular system of the larynx holds out to the last against the morbid process, although tubercle may pursue its ravages in the connective tissue between the fibres.

(b) Amongst the non-tubercular ulcers are found some which arise from disease of the racemose follicles. These have been studied by Rindfleisch²¹ and Rheiner²² with especial care. The pathological process appears to be at first quite similar to that which constitutes the characteristic lesion of follicular or granular sore-throat. These ulcers occur, of course, exclusively in the track of the glands—i.e., at the base of the epiglottis, over the arytenoid cartilages and ventricular bands, below the vocal bands, and in the trachea. The follicles become distended with inspissated secretion of a caseous or curdy consistence, which exudes slowly from their ducts, appearing at the orifices as a white patch or a thread-like filament. But in laryngeal phthisis this stage, which is permanent in the milder disease, is of brief duration, for a destructive process is quickly superadded, pus is mingled with the caseous contents of the gland, the duct is dilated and eaten out, and the whole mass discharged, leaving a cup-shaped pit or cavity, which secretes pus, and soon forms a progressive ulcer. These are the accretions some advocates of the tubercular larynx formerly exhibited as tubercle, to be triumphantly proclaimed in error by their opponents, who had demonstrated the real nature of the follicular lesion.

(c) A third kind of ulceration has also been brought to notice by Rheiner.²³ He describes it as originating in an infiltration of the subepithelial layer of the mucous membrane with cells and nuclei. He explains it to proceed from the peculiar vulnerability of the soft parts observable in tuberculosis; and hence all parts of the larynx exposed to pressure during the varied activity of the organ are liable to be attacked by an inflammatory cell-proliferation. Although Ziemssen accepts this view unhesitatingly, Heinze²⁴ rejects it altogether, alleging several not very cogent reasons for his dissent, such as that the vocal processes do not come into contact during phonation on account of adjacent swelling, etc. It must be remembered, however, that Heinze²⁵ is inclined to attribute a more universal rôle to tubercle in the larynx than it clinically appears to possess; although, by his own showing, in eight out of forty-seven cases examined microscopically he could not demonstrate the tubercle.²⁶ Logically it must be confessed there is good reason to believe in the correctness of Rheiner's hypothesis. Why, for instance, is the inter-arytenoid fold generally the first part attacked, unless by reason of the constant pressure to which it is subjected during phonation? Why have ulcers such a predilection for the arytenoid cartilages and under-surface of the epiglottis—parts squeezed to death, as one may say, when

²⁶ Heinze rather dogmatically remarks: "The so-called phthisis of the larynx and trachea is henceforth to be applied only to tubercle of the laryngeal and tracheal mucous membrane;" and, at the same time, he proves that in his period, before the bacillus, the ulcers could only be recognized as tubercular at the post-mortem table with the microscope.

swollen by being jammed against each other in deglutition? Why are the edges of the vocal bands so prone to ulceration, even when no other part is affected, not only in laryngeal phthisis, but in syphilis and simple chronic catarrh? Because it is precisely these edges that bear the strain of extension and vibration during speaking, coughing, etc., being more constantly in action than any other part of the larynx. Similarly, the tissue covering the vocal processes is subjected to the most destructive kind of pressure by being stretched and strained over those hard points in phonation, even though they may not actually touch. So far, therefore, from allowing that Heinze "has disposed of" Rheiner's views,²⁷ a little reflection will show them to be as firmly established as ever.

(d) Finally, we have the shallow extensive erosions of the larynx and trachea noticed by Trousseau and Belloc as being uniquely found in phthisis. These scarcely penetrate the subepithelial layer of the mucous membrane, and have a flat grey floor, often resembling, as Förster remarks,²⁸ a diphtheritic exudation. Their margins are neither elevated nor indurated, and they are conspicuously absent on the anterior wall of the wind-pipe, where, it may be assumed, the mucous membrane is least exposed to the constant passage of sputa. The presence of such solutions of continuity is thought by Ziemssen²⁹ to force on us the acceptance of the theory of a corrosive action of the pulmonary sputa. Yet Förster thinks that even these may be tubercular. Whether this corrosive action is to be considered as something distinct from the infective nature of the bacillus, or whether the conflicting opinions may not be reconciled by allowing a local denudative power to the bacillus, especially when resting in congregation on a morbidly tender mucous membrane, are propositions awaiting solution.

The subject of perichondritis, leading to necrosis and caries of the cartilages of the larynx, does not come within the scope of this article, although the destructive ulceration of laryngeal phthisis naturally culminates in this lesion. In the cases examined by Heinze,³⁰ it was not observed in connection with undoubted non-tubercular ulceration.

Diagnosis.—In the earliest stages the advent or existence of laryngeal phthisis must be chiefly a matter of surmise, and the practitioner should be on his guard against predicting the misery of this disease for every consumptive patient who may fortuitously become the subject of some intercurrent congestion or catarrh of the larynx. When, however, pronounced symptoms of chronic laryngitis are present, or the peculiar tumefaction of the larynx is observed, the approach of destructive ulceration may be regarded as a matter of course, provided there is no doubt as to the chest lesion. But in the absence of decisive pulmonary evidence the ulcers have not, theoretically at least, pathognomonic characters. Fränkel,³¹ however, thinks that the lenticular ulcers with the red areola can be recognized unmistakably in the first periods of loss of substance. The same authority advises the examination of the laryngeal discharges for bacilli. For the purpose a quantity may be obtained by wiping it off the surface of the ulcers with a brush, the operation being carefully watched in the laryngeal mirror. By Ehrlich's method of staining and the

microscope the inquiry is completed. In practice it is seldom possible for the laryngoscopist to be mistaken about a case of ulcerative laryngeal phthisis. On the one hand the diagnosis is almost invariably affirmed by the state of the constitution and chest, whilst on the other it is clearly negated by the well-known collateral phenomena so prominent in syphilis, carcinoma, and lupus, the only other chronic maladies in which destructive ulceration occurs. The occasional coexistence of one of these diseases with consumption must not, of course, be lost sight of.

Prognosis.—All that may be doubtful respecting the course and termination of a case of pulmonary consumption may be practically considered as removed by the supervention of laryngeal phthisis. This manifestation of tuberculosis not only assures, but also hastens, the fatal issue. The indefinite prolongation of life so common in purely pulmonary phthisis, as well as the possibility of a virtual cure, must not be contemplated in the presence of phthisical ulceration of the larynx. All laryngologists may be taken as in agreement on this point. Ziemssen³² thinks that particular ulcers sometimes cicatrize, but without retarding the course of the disease, as the general destructive process continues unchecked. Out of many hundreds of cases Mackenzie³³ has only seen four in which the malady could be set down as arrested. Krishaber³⁴ believes that the form supposed to be initial may have an indefinite duration, but from previous statements in this article it will be readily understood that these instances cannot fairly be reckoned as laryngeal phthisis until the ulcerative stage is reached. The latter author, like the rest, allows that the disease is hopeless when fully developed. Mackenzie gives statistics as to the duration of life after the laryngeal symptoms have become prominent. Eighty-eight cases out of one hundred persons who died of the disease were fatal in periods varying from six months to two years and a half. Of the rest the longest survival was forty-nine months.

Treatment.—In addition to the treatment of pulmonary consumption, all laryngologists are agreed as to the palliative value of certain local measures in laryngeal phthisis. These belong chiefly to three classes—viz., application of astringents, of sedatives, and the performance of tracheotomy.

1. Astringents are of use in modifying the condition of ulcers, especially by reducing their irritability, and there is no doubt but that they will often cause the non-tubercular ulcers to heal. Solution of perchloride of iron (60 to 120 grains to the ounce) is probably better than any other remedy of this class. It may be applied to the larynx with a brush once or twice daily.

2. Sedatives are imperatively demanded when the pain of deglutition is severe. Under this heading morphia alone needs prominent mention. If administered by the mouth or hypodermically it is effectual; but when applied locally experience shows that it acts, not only directly, but in a more restricted manner as regards the laryngeal symptoms. An eighth of a grain of muriate or acetate of morphia mixed with three or four times its bulk of powdered starch may be blown into the larynx through the curved tube once daily, or every morning and evening. This insufflation is decidedly superior to any other means of applying the sedative. Some practitioners, however, prefer the drug in a fluid vehicle, mixed with glycerine, for example.

³⁴ *Op. cit.*, p. 661.

Krishaber employs a solution in cherry laurel water of equal parts of extract of opium and extract of belladonna, about six grains of each to the ounce.

3. Although tracheotomy in laryngeal phthisis has not found much favor in this country, it has been extensively practiced in America and on the Continent. Unless for the actual relief of dyspnoea, the operation has not hitherto been resorted to by British practitioners. Its performance is advocated, however, at a comparatively early stage, in order to bring the larynx into such a state of rest as will facilitate the healing of ulcers, or check their tendency to spread as far as it may depend on mechanical irritation. The experience of Leferts supports this view, and his opinion is that "tracheotomy when not left till too late is to be recommended in all proper instances, through being sometimes curative and generally palliative as a means of prolonging life by relieving suffering."

ON THE TREATMENT OF MEASLES.

By D. MACLEAN, M.D. Glas.,

Physician to the Glasgow Public Dispensary, Chest and Throat Clinique.

In the present prevalence of this disease it may not be out of place to call attention to a method of treatment which has been found, in my hands, of what might be called universal success. Considering that this disease is one that must be passed through by almost all members of the human family at some period of their existence, we may take it for granted that it is something essential that the human frame should undergo for the purpose of perfect health. Taking also for granted that it is the cause of cutting short many lives, it behoves us to take advantage of every means that can abbreviate the duration of the disease and diminish the mortality which so unhappily springs from it. We see every now and again in the journals and newspapers that an epidemic of measles has taken place in such and such a quarter, and that it was necessary to close the schools, etc. Nor is it only in our own country that we learn of so many deaths taking place, but we read of how its fearful ravages decimate whole populations, such as have recently taken place in Fiji. It thus seems essential that any form of treatment (for we cannot apparently prevent the onset) that can diminish the mortality must be of paramount importance whenever these epidemic or even sporadic cases appear. The form of treatment which I propose to lay before the members of our profession, and the remedies which I have been in the habit of using for a good many years, will enable them to try the same in their own practices, and ultimately refute or corroborate the conclusions I have long ago arrived at.

As this disease is considered one of the zymotic class, we have in its treatment, to consider, principally two things—(1) the management of the ferment, or whatever it is; and (2) the management of the effects of this ferment upon the system. The most marked of these latter present themselves to us in the effects of the ailment upon the mucous membranes. The greatest action of the disease, as we all know, is upon the mucous membrane of the lungs, and it is from its action there we have the immediate cause of the ensuing death, or the prolonged ill-health afterwards. We have thus clearly set before us the line of action to follow:—(1) To relieve the congestion of the mucous membrane, which is the immediate cause of danger; and (2) to destroy or reduce the violence of

the disease itself. This I have been in the habit of doing, I believe successfully, by giving (say to a child of two or three years of age) a teaspoonful in water of the following mixture every three hours:—Ipecacuanha wine, half a drachm; syrup of squilla, half an ounce; quinine, two grains; acetate of ammonia solution to two ounces. Of course the quinine is increased according to age. We have thus in this mixture a stimulating expectorant and diaphoretic to relieve the tension in the mucous membranes and the skin, and also in the quinine a specific to destroy or abate the violence of the primary ferment. It may be necessary to add to or modify the form in which this plan of treatment is carried out; as when the irritation and cough are persistently great, then the addition of a little tincture of hyoscyamus is all that is necessary. So with the quinine; sometimes the stomach is so irritable that it is necessary to omit it from the mixture; but as it is essential that it be introduced into the system for the destruction of the ferment, it can be administered separately by giving it in powder, mixed with saccharated carbonate of iron, which diminishes the irritant action of the quinine that takes place when the drug is given alone.

This form of treatment for measles is good in all types of the disease, whether the attack be mild or severe, and more especially valuable when we have that dangerous form in which the eruption is of a deep-purplish color, a form which is generally recognized as being the most fatal. This style of treatment I have followed for a number of years. I have seen many cases, and, as a justification for submitting it to the notice of the profession, I do not remember having signed a certificate of death for either the disease itself or its effects.

Glasgow.

ON A CASE OF CYSTIC POLYPUS OF THE RECTUM, COMPLICATING PARTURITION.

By P. ENGLEDEUX PRIDEAUX, M.R.C.P. Lond., etc.

Mrs. H—, the wife of a tradesman, aged twenty-eight, was delivered of her first child on May 12th, 1881. The labour was long and tedious; the first stage was very prolonged, the os dilating very slowly. Then the head was arrested in the pelvis, and, in spite of very violent pains, made no progress. I could discover nothing to account for this; the pelvis seemed well-formed and of good development. After waiting for some time, in deference to the patient's wish, and finding the pains ceasing, I applied Barnes' long forceps, and after using some force, delivered her of a male child, which appeared to have been dead some days. The perineum was ruptured; I placed a deep stitch in it, and it healed completely in a few days. The patient progressed very well, and was convalescent in the ordinary time.

The second labour took place on April 27th, 1882. The first stage was very long, lasting over two days, accompanied by a persistent dragging pain on the left side of the body, which seemed to be from one spot. I noticed that the rectum seemed full high up, and thinking it was caused by feces, ordered an injection, which however brought away nothing. The labour progressed very slowly, and the patient complained of this intense pain, which seemed as much as she could bear, and was evidently quite different from the labour pains themselves. Finding that she was becoming exhausted, and the head did not advance in the least, and seemed arrested high up, I introduced Barnes' long forceps, and for a long time was unable to make any impression with these; at last, after con-

tinuous and firm traction, the head seemed to slip past very suddenly, coming out through the external orifice before I expected it, causing extensive rupture of the perineum right through into the anus. The rest of the labour was easily accomplished, the child, a fine girl, being born alive. I put in several deep wire sutures in a manner I always have found successful; banded the patient and left her fairly comfortable, but still complaining of pain in the side, for which I gave her a dose of opium. At night I found the abdomen distended apparently with flatus. I ordered a draught of morphia and a hot bran poultice. The next morning the abdomen was more distended, but no excessive tenderness; still complaining of acute pains from one spot. Temperature normal. The abdomen went on distending all this day and seemed full of gas, little or none being passed. There was no tenderness over the general surface. Temperature at night 99.5°. There was slight sickness in the night, otherwise food had been taken very well; gave some morphia and bismuth. On the morning of the third day the abdomen was swollen and tense, like an immense drum, evidently enormously distended with flatus; no pain; temperature 99.5°; pulse good, but somewhat quickened and varying. She looked well and cheerful. I made an examination, and found in the rectum a large swelling about the size of a foetal head, freely movable, and which I thought at first to be intrussuscepted bowel coming down. I was the more confirmed in this as I thought I detected a central opening. After spending a long time in trying to reduce this by gentle manipulation, I sent for, and obtained the advice of, Mr. Wm. Liddon, of Taunton. He made a careful examination, and came to a conclusion similar to mine. We found, however, that we were unable to pass a catheter up what appeared to us to be the central opening, whilst we found we could pass a long tube up between the tumour and the rectum; this let off a quantity of gas, and materially relieved the patient. As the case was so obscure, we determined upon reopening the perineal wound, and enlarging it up the recto-vaginal septum, thus exposing the tumour to view, the patient being placed in the lithotomy position. We at once saw that it was not covered with mucous membrane; its surface was rough, and much injected. The part we had taken for an opening was a dimple with a small appendix to the tumour. We then dragged it down, and found it to be a cyst as large as a foetal head, with a long narrow pedicle, reaching far out of reach up the bowel; we could make out at least six inches; we then tied it in two places, cut it off with scissors, and allowed the rest of the pedicle to remain. The tumour when opened contained about half a pint of a thick albuminous fluid, with one part a little thicker than the rest; its wall was found one-eighth to a quarter of an inch thick, much bruised and ecchymosed in parts, probably from the delivery by the forceps. After removing the tumour the abdomen soon went down, with great relief to the patient. The rent was carefully stitched with deep and superficial sutures, and a morphia suppository was inserted. The further progress of the case was satisfactory, and would have been more so but for an intractable diarrhoea which set in soon after the removal of the tumour. It appeared to me that the tumour had acted as a chronic obstruction to the bowel, and its removal, combined with the bruising of the bowel by the forcible delivery, were the causes of this diarrhoea. I found that with apomate powdered chalk and subcarbonate of bismuth frequently administered, together with morphia suppositories, I just managed to keep in check this diarrhoea, but it un-

fortunately retarded the healing of the wound in the recto-vaginal septum, and ultimately a small opening was left. By frequently touching the edges of this with acetum lyttæ it has, however, so contracted that it has not proved a source of annoyance to the patient. With regard to the rest of the details, the progress of the case was everything that could be desired, the patient never had a bad symptom, the temperature never rose above normal, there never was any tenderness over the abdomen, and the dragging pain ceased, and the convalescence of the patient became established in a time very little longer than after ordinary parturition.

The case is an exceedingly rare one, there being but one or two recorded cases, and the length of the pedicle making it quite unique. I am of opinion that the tumour existed during the first labour, and grew in size from the bruising inflicted on it by the delivery, and that it lay usually in a bend of the colon, but was pushed down in the second delivery by the descending child, and then blocked the bowel completely, like a blown-out Barnes' bag. There had been for some years trouble with the bowels, in the shape of constipation, but nothing to excite suspicion of any tumour.

Wellington, Somerset.

ON A CASE OF SPINA BIFIDA MASKED BY A FATTY TUMOUR.

By ARTHUR JEFFERSON, M.R.C.S.,

House-Surgeon, York County Hospital.

MARTHA M—, aged four, was admitted to the hospital under the care of Mr. Jalland in October, 1882. Her mother stated that from birth the child had had a tumour on her back, which lately had become larger, and commenced to give rise to a certain amount of pain, and that also there had always been more or less incontinence both of urine and faeces. On examination the patient presented on her left buttock a largish tumour, which gave to the gluteal region a unilateral Hottentot confirmation. The tumour had no apparent boundary, but gradually shaded off into the trunk and leg on the same side; on firm pressure no diminution in its bulk occurred; on gentler manipulation it gave to the fingers a semi-fluctuating sensation. The upright position caused no apparent increase in the tenseness of the enlargement, but in the erect posture the unilateral nature of the tumour, so very distinct in the prone position, was somewhat modified, and it became apparent that the vertebral column ran beneath the swelling, about one-quarter of which was to the left of the spine, the remaining three-quarters to the right. For about ten days the child was watched, and it was found that there was persistent incontinence of urine and occasional incontinence of faeces. It was now decided to explore the tumour with a trocar and cannula. This was accordingly done under the spray, the puncture being made to the left of the swelling, over the spine; but though many different-sized trocars were used still no fluid came away. In order to explore further an incision was now made vertically down the swelling, and carried through the fat to a depth of about two inches. On the sides of this incision was seen a stratum of vascular connective tissue which divided the fat into two layers, a superficial, thin, normal layer and deeper abnormal one. These two layers were now separated from one another; but no lateral limits to the new fat being found, it was resolved not to enlarge the primary incision, but simply to remove through it as

much of the fatty growth as could be got at. While dividing the deep attachments a cyst was suddenly punctured, and about half an ounce of clear fluid gushed out. The wound was now sewed up and a gauze dressing applied. After the operation the child suffered no pain; on the third day, the bandages having become moistened by urine, the wound was dressed. There was no pus, and it looked healthy; it was impossible to say whether any serous oozing had occurred, the dressings being so wetted by urine. On the night of this day the child, who previously had had no bad symptom, vomited once, her temperature being, as on all previous nights, a little over 98° F. On the following morning, fourth day after the operation, it was reported that the patient had been unable to keep anything down, her temperature was 96°, her body felt very cold, her pulse was feeble and slow, and she seemed very listless. These symptoms appeared to point to carbolic poisoning; the urine, however, could not be taken as a guide, being passed into a mackintosh in contact with the carbolized dressings. Eucalyptol dressings were applied, and stimulants with digitalis administered. In the evening the child's condition was more serious; she was quite conscious, but more listless. The vomiting now occurred about every ten minutes, quite irrespective of the taking of food. The surface of the body was peculiarly cold, the temperature still being 96°, and the radial pulse could not be felt. On stethoscopic examination the heart's action was found to be very feeble, the pulsations being much increased and varying in rapidity, with occasional intermissions. It was now evident that the vomiting and other symptoms had some cerebral cause. The child was wrapped in blankets, hot water bottles were applied, and enemata of brandy and digitalis administered at frequent short intervals. The symptoms continued, and ended the following morning in a convulsion, during which the patient died.

Post-mortem examination.—On forcing apart the edges of the incision, which had partly united, the opening into the cyst was seen; a director being passed through this the cyst was opened up. The cavity thus exposed was about the size of a pigeon's egg, smooth and glistening on its inner surface, bounded above by the lamina and spinous process of the first sacral vertebra, coming out from beneath which was the termination of the spinal cord, which, passing downwards and backwards, was attached to the cyst-wall, the spinal cord, parietal layer of arachnoid, dura mater, and fat being at this point fused into one mass. There was no cerebro-spinal fluid even on placing the body erect. On opening the skull, the sinuses and veins of the brain were found to be enormously engorged with blood, the ventricles were destitute of fluid, and the choroid plexuses much distended. Save some pulmonary congestion, the other organs of the body were apparently healthy.

Remarks.—In this case there was no internal hydrocephalus, the cerebro-spinal foramen being patent, therefore an opening into the spinal canal having been made, the cerebro-spinal fluid was naturally drained off, and its reaccumulation prevented. In consequence of the constant drawing off of this cerebro-spinal fluid the vessels of the brain, being no longer subjected to their normal pressure, with more or less rapidity dilated; it may be supposed that this dilatation increased gradually, step by step, until the third day, when the brain became so much engorged as to fall and press with more or less force on its base, on which the unsupported cord would also drag heavily. The resultant of these two forces—the weight of the brain and the drag of the cord—would pass down-

wards and forwards through the medulla oblongata, which would be pressed on to the basilar process of the occipital bone, the fourth ventricle being flattened out on the top of it. As a consequence of this, the various nuclei in the floor of the fourth ventricle became irritated; the first of these centres roused to activity would seem to have been the vomiting centre; next the vaso-motor and cardio-inhibitory centres, producing on the one hand pallor and coldness of the surface, in which the cerebro-spinal congestion would assist, and, on the other hand, weakness and irregularity of the heart's beat; finally, just before death, the respiratory centre was also involved and the asphyxial convulsion occurred which terminated life. This case illustrates some of the consequences of the withdrawal of the cerebro-spinal fluid. It is possible that had the child been placed face downwards, with its buttocks elevated, its life might have been prolonged.

York.

A CASE OF EPILEPSY.

OBLIVIOUSNESS OF DANGEROUS ACTS; MEDICO-LEGAL BEARINGS; VALUE OF PERCUSSION OF THE SKULL.

By A. ROBERTSON, M.D., F.F.P.S.G.,

Physician to the Towns Hospital and City Parochial Asylum, Glasgow.

THE following observations are largely based on a case which lately occurred in this hospital, of which a careful record was made by my late assistant, Dr. Williams, now of the Denbigh Infirmary. His report is as follows:—

W. K—, aged forty-five, a soldier, was admitted on Jan. 25th, 1882. Five years before admission he had a sunstroke in India. Epileptic seizures set in shortly afterwards, and recurred at intervals of from a month to six weeks till the time of his admission into the hospital. Under a combination of the bromide and iodide of potassium, half a drachm of the former and ten grains of the latter, thrice daily, the intervals were somewhat prolonged. On Feb. 23rd of this year he had a convulsive fit, which left him irritable and quarrelsome, but apparently quite conscious of all his actions. On the 24th, while in this mood, he suddenly attacked and knocked down an old man who was passing him in the ward, though there had not been the slightest quarrel between them. Next day he denied having struck him, and at the same time said that he had no recollection of anything that happened on the previous day. His whole bearing in saying so impressed me with the truthfulness of his statement. There was no further violence nor recurrence of the fits, but he was unsocial and somewhat obtuse. He complained of pain in the head, especially on the left side and anteriorly. The pupils were slightly dilated. On April 14th slight shivering occurred, and the axillary temperature was found to be 103° F. Headache was severe, and still most pronounced on the left side. I percussed the skull carefully. The patient stated that the taps of the finger did not cause pain on the right side or back of the head, but that they were very painful on the left side, in front of the ear, forward to the middle of the brow. Leeches were applied over the painful region, and mercurialunction prescribed. The symptoms, however, became more serious, and he died comatose on May 16th.

Necropsy.—There was about an ounce and a half of serous fluid under the arachnoid and in the ventricles; within the dura mater, on the left side, over the entire frontal lobe, and extending downwards to the base, there was a thin organized false

membrane, which seemed to have no adhesions either to the dura mater or arachnoid. The brain was firm; the specific gravity of the white substance in the frontal region was 1047.

Remarks.—Much attention has been given by Dr. Hughlings-Jackson and others to the mental automatism which not unfrequently occurs in epilepsy, particularly after attacks of petit mal. In these cases purposive acts are performed, sometimes nearly correct in themselves, but at improper times and places, and without the consciousness of the actors. But there is a condition following such seizures in which the mental defect is even less than that just stated, where consciousness is only very slightly impaired, where there seems only a little confusion of mind, scarcely noticeable to superficial observation. The remarkable feature of this state is that the patients may maintain a conversation, apparently correct or nearly so, and perform acts, of which they have not the slightest recollection a few hours afterwards. This is illustrated by W. R.—'s case. He knocked down his fellow-patient without the least provocation, though seemingly aware of what he was saying and doing, both then and afterwards in the course of the day; yet next day he declared, and I believe truthfully, that he had no recollection not only of that act of violence, but also of all the other events of the next few hours. The question suggests itself, Had he killed the old man at the time he struck him, ought he to have been held responsible for his death? I think not; at least, not fully so. A few months ago I was engaged as medical witness (case of George Miller) in a trial for murder by an epileptic, in which the accused, like W. R.—, declared that he had no remembrance of the fatal act, nor of what happened, for at least half an hour afterwards. The main facts of the case are as follows:—G. Miller, a soldier, who had been in the Egyptian campaign, was discharged on Dec. 30th, 1882, on the breaking up of his regiment in a small town about ten miles from Glasgow. He drank freely in the course of the afternoon, at night reached the city by train, when, being unable to take care of himself in the streets, he was conveyed to the district police-office. There he was able to tell his name, etc., and walked upstairs to a cell with assistance. He was laid on a fixed wooden bed beside another drunken prisoner, who was asleep at the time, and locked up with him about 8.15 p.m. The latter was stated by those who knew him best to be very inoffensive, and not quarrelsome either in drink or out of it. They were seen by the warder five different times at short intervals, the last time being at 10.45 p.m., and always found asleep. Twenty minutes later, when again visited, the accused was sitting at the side of the cell, with his arms crossed, and his comrade in the middle of the floor, lying with his face down, dead. The head of the deceased was fearfully bruised, and some of his ribs were broken. The conclusion arrived at was that the soldier had jumped on him or kicked him to death with his heavy boots. The gaoler stated that the accused said, on being questioned respecting his comrade's death, he knew nothing about it, and while saying so, appeared cool and collected, and so correct in every way that, had nothing happened, the officer in charge would have allowed him to go free. He was taken to the bar and formally charged with the crime of murder; the lieutenant on duty testified that he was apparently quite conscious of what was said to him. Thereafter he was removed to a cell, where he spoke for a short time freely about his Egyptian experiences to the officer appointed to watch him, and then fell asleep. He slept soundly for nearly five hours. When he

awoke he was told about his crime, but he appeared quite incredulous, and declared that he had not the least recollection of it or of any of the after circumstances. It was ascertained that he had been subject to attacks of petit mal, and that on one occasion he had a convulsive seizure. He had also been convicted of inflicting a severe blow on a woman, an entire stranger to him, who was passing him quietly in the street; he denied all knowledge of this assault also. He had likewise about two years previously made a determined attempt at suicide.

This history points to the fatal attack as having been of an epileptic character. No doubt the prisoner had previously been indulging in alcoholic liquors, but this does not satisfactorily account for his condition when first seen after the homicide. The seeming cool composure and indifference which he then displayed, the failure to realize his position, and the forgetfulness of the act, as well as of the events of the next half hour, all indicated a really imperfect consciousness, even though to ordinary observers he was apparently fully aware both of what he was saying and doing. At the same time the epileptic seizure, which I believe occurred on his awakening from the drunken sleep, was itself probably due to the action of the alcohol on his weak and susceptible brain. It only further remains to be said that the jury found the accused to have been of unsound mind at the time he killed his comrade in the cell, and he was sentenced to be confined in the Criminal Lunatic Asylum during Her Majesty's pleasure.

It is not improbable that the objection may occur to some minds that, after all, the chief actors in both of these cases may not have been so oblivious as they alleged and appeared to be, it being so very much their interest, and especially G. Miller's, to deny all recollection of their criminal acts. Such objectors will, I think, admit that the following case, very similar to the others so far as the mental condition is concerned, is free from that doubt. A gentleman, aged fifty, whom I see occasionally, has been subject to the minor, and much less frequently the major, attacks of epilepsy for several years, the intervals between the seizures varying from a week or two to some months. Though mentally not now quite equal to his former self, he is still active and intelligent, and, what is specially to be observed, possessed of fairly good memory. On several occasions he has had attacks of petit mal when attending to his occupation, and has afterwards found his way downstairs and through busy streets, returning quite correctly to his place of business, but entirely unconscious of all that had happened in the intervals, lasting for from five to twenty minutes. It is not known how far he may have seemed intelligent and correct to others while walking in that condition. What I have next to mention is, however, more to the point under consideration, and was told me by his wife, a highly intelligent lady. One afternoon, about four months ago, while he was seated on the sofa at home, she observed by the movement of his lips and one of his hands that he had taken one of his "turns." The ordinary medical attendant of the family was sent for, and arrived within a quarter of an hour. By this time the patient was apparently quite conscious, and conversed correctly with his medical friend for about five minutes. About half an hour after the latter had left the house, some reference was made by the patient's wife to the doctor's visit and his instructions, when she found that he had no recollection of his having seen him, and indeed positively insisted that the doctor had not called that day.

In W. R.—'s case the exact correspondence between the painful area on percussion of the head and the extent of the false membrane within the dura mater, so far as it could be ascertained, was very striking. Would it not have been warrantable, as my friend Dr. Macewen, of this city, suggests to me, to have trepanned the skull and removed the false membrane? In the light of the necropsy this might have been done, and with probable advantage, as the irritation due to its presence was, I think, the immediate cause of death. In any future case of a similar kind, in which percussion clearly defines a painful region, I should be disposed to try trephining, in the event of no improvement resulting from ordinary treatment.

As the method of diagnosis by percussion of the skull is still comparatively new, I may mention that there is at present in this hospital a patient in whom it revealed a painful area over the motor region of one side of the brain. He had been long subject to convulsive seizures, mainly unilateral, and has greatly improved since the application of a series of blisters over this region.

Glasgow.

ON THE USE OF CARBOLIZED SAWDUST AS A DRESSING IN ANTISEPTIC SURGERY.

By H. P. SYMONDS,

Surgeon to the Radcliffe Infirmary, Oxford.

ONE of the drawbacks of the usual antiseptic dressing is the rapidity with which the discharges come through on the first day or two after operation, often necessitating the redressing of the case within a few hours. To prevent this, and yet not to interfere with the aseptic condition of the wound, is a distinct advantage both to the patient and the surgeon. The material I have used recently in a considerable number of cases is coarse sawdust, soaked in (1 in 10) solution of absolute phenol and spirit of wine, then allowed to dry slightly so that the spirit may evaporate, leaving the sawdust charged with carbolic acid. When used it is enclosed in a bag made of several layers of gauze, and applied outside the deep dressing, the usual external dressing being put over it. The sawdust thus takes the place of the padding of loose gauze which is generally used. Its absorbent power is very great, and it has the additional advantage of keeping up an equable pressure on the divided tissues. I find that fourteen ounces of sawdust will readily absorb about one pint of fluid.

The following cases in which this dressing has been used form a successive series, taken without any selection.

CASE 1.—Amputation through the middle of the arm for disorganization of the elbow-joint and necrosis of the humerus. The operation was done on July 24th. The stump was dressed at the end of twenty-four hours in order to remove the drainage-tube. On July 30th the dressings were changed and sutures removed. The wound was quite healed, with good union throughout. The patient was discharged from the infirmary seven days after operation.

CASE 2.—A woman, aged sixty-one, with extensive scirrhus of the breast. On August 10th the whole breast was removed, and the axilla cleared of glands. Two drainage-tubes were put in the wound. Dressings changed on the 12th to remove the tubes, and again on the 17th, when some of the sutures were taken out. On the 19th the wound was thoroughly healed, and the patient left the infirmary.

CASE 3.—A man aged forty-eight. Amputation of forearm for large sarcoma in the back of the hand. Operation done on August 3rd. Drainage-tube removed in twenty-four hours. Wound dressed again seven days after the operation, when complete union had taken place.

CASE 4.—A middle-aged woman, with compound dislocation of the elbow, admitted August 11th. She had a small wound on the inner side of the right elbow. Both bases were dislocated backwards, and the inner condyle chipped off. The joint was dressed antiseptically, a counter opening made, and a small drainage-tube passed through. This was removed in twenty-four hours, and the dressing not changed again for four days. No soaking through took place, and the wound remained aseptic. The highest temperature 99.4°.

CASE 5.—Removal of an adenoma from the breast of a girl aged eighteen. This case occurred in private practice. Drainage-tube removed in twenty-four hours. Dressed again on the seventh day. The incision was quite healed.

In all these cases complete primary union took place without any formation of pus. In only one did the temperature reach 100°, and that on the day after operation, after which it became normal. I have not quoted these cases as being at all remarkable, but merely as common instances in antiseptic surgical practice in which the sawdust dressing was used. Surgeon-Major Porter, in "The Surgeon's Pocket-book," states that he has used sawdust as a dressing in suppurating offensive wounds; but I am not aware that it has been tried, when prepared in the way I have described, in antiseptic dressing. The three points in its favor are its powerful antiseptic qualities when saturated with carbolic acid, its great absorbent power, and its adaptability to any surface. I may add that the sawdust should be coarse, as I find that if it is very fine it passes through the gauze and irritates the skin.

Oxford.

ACUTE RHEUMATISM AND PHTHISIS.

By J. GORDON BLACK, M.D. Lond.

IN THE LANCET (October, p. 313) Dr. Austin calls attention to acute rheumatism as a premonitory symptom of phthisis, and gives the histories of four cases in illustration. The following particulars of a case attended by me last year may perhaps be of interest in connection with this subject.

On March 6th, 1882, I first saw a pale, delicate-looking young woman, aged twenty. Both father and mother were dead, the former of phthisis, and a sister was then suffering from that disease. My patient had been doing rough hard work beyond her strength in a cold damp atmosphere, for some months. At the previous Christmas she caught cold and a cough ensued. She had, however, been away from work only two days. The symptoms were on examination:—Short dry cough with pain under left axilla, sickness and vomiting of food, sleepless nights, and free perspiration. Pulse 100, weak, and pupils dilated. Tongue red in middle, furred at the sides. Temperature only slightly above, and respiration, normal. Menses regular, but discharge too pale. Some rough breathing below left clavicle; no dulness or crepitation. No increase of cardiac dulness, but sounds unduly accentuated. At this visit I was undecided as to the exact nature of the attack, fearing some lung mischief or impending febrile disorder. A diaphoretic and expectorant mixture was prescribed and the affected side ordered to be poulticed.

ticed. Next day I found that the cough and sickness had entirely left her. The pain was still bad in the side, and perspiration continued. Temperature 102°, pulse 100. A soft murmur was now heard with the first heart sound, loudest over the pulmonary cartilage, slightly conducted towards the apex, but not heard over the second right cartilage. The right knee and ankle were swollen and tender. Thus the affection had developed into rheumatic fever, and the signs of lung implication suddenly disappeared. Salicine treatment happily soon gave relief to the distressing symptoms, and by the second day of its use the patient was comparatively well. The cardiac murmur became much less audible, but never went entirely away. At the end of March the patient being rosy and plump, in complete contrast to her previous condition, was allowed to go to a farmhouse in the country.

On April 17th, a few days after her return, I saw her again, and was shocked at the serious change which had occurred. She was now in bed, complaining of excessive muscular weakness. The cough, fever, and vomiting of food had returned worse than ever. Some dulness was now noted in both infra-clavicular spaces, and at the top of the sternum. Pectoriloquy and mucous râles were heard on the left side below the clavicle, whilst on the right there was double respiration. Expectoration was copious and nummular. Pulse 120; temperature 101°. By April 27th the above symptoms had become greatly aggravated. The expectoration was tinged with blood, and there were signs of a vomica at the top of the left lung. For the next few weeks the disease progressed with the fearful rapidity of so-called "galloping consumption;" but afterwards, curiously enough, became quite chronic. The appetite had never failed, and from first to last colliquative diarrhoea was absent. Thus were the powers of nature sustained until the patient had become a veritable skeleton. Death occurred on the 24th of November.

The succession of symptoms above detailed arrested my attention as being unfamiliar, and I was therefore much interested to observe that Dr. Austin had recently attended four somewhat similar cases. Judging by my own experience, I should say that acute rheumatism is a rare complication of phthisis. The text-books are almost silent on the subject, nearly every other ailment, however, being mentioned in that category. Under the head of Acute Rheumatism we find no allusion to the existence of a tubercular variety, though others, such as scarlatinal and gonorrhoeal, are enumerated. At one time the phthisical and rheumatic diatheses were even thought opposed to each other. The following exceptional reference is made towards the end of the late Dr. Hughes Bennett's article on Phthisis, in Reynold's "System of Medicine:—"Pericarditis and other inflammatory diseases may occur, occasionally gout or rheumatism." And from the construction of what immediately follows, one gathers that Dr. Bennett did not consider such complications to bear "an essential or constant relation to phthisis."

Now, such a view seems to me more in accordance with symptoms than Dr. Austin's theory that tubercular deposit in the affected parts is the cause of the rheumatic manifestations. It is noticeable that when tubercle occurs in different organs and membranes during the course of phthisis pulmonalis, it does so as part of a general constitutional affection, with which the local developments do not tend to interfere and which the latter do not mask. It is perfectly different, however, when rheumatic fever intervenes. This seems completely to replace the signs of pulmonary affection by others peculiar to itself, which then

have their ordinary course and termination. Further, the well-known tendency of tuberculosis to produce chronic inflammation and ulceration does not accord with the equally familiar temporary and changeful character of acute rheumatism, in which disease ulceration is exceptional. If Dr. Austin's theory were correct, one would look for ulcerative endocarditis or serious disorganization of joints in cases of phthisis complicated by rheumatism. We know that such results are not uncommon where other specific agents of inflammatory action are present, such as gonorrhoea or scarlatina. Another argument may be adduced from a consideration of the results of treatment upon the phases of disease under notice. The well-known power of salicine to control acute rheumatism, a good illustration of which is furnished by the case related above, contrasts strongly with its utter uselessness in checking tuberculosis. If both sets of symptoms in my case had been due to one general cause—viz., tubercle—then one fails to understand the marked difference observable in the effects of salicine. Considered in connection with pulmonary consumption, I am therefore inclined to regard acute rheumatism as a somewhat rare accidental complication of the former, to which malady it bears no necessary relation. Although it cannot consequently be properly regarded as "premonitory," yet it is well to remember the possibility of its advent as an early complication. Unless this be kept in view during attendance upon a delicate patient suffering from rheumatic fever, especially where there is a family history of phthisis, a too favorable prognosis may be ventured, to the disappointment of the friends and possible discredit of the medical attendant.

Harrogate.

ON A CASE OF COMBINED SCROTAL AND ABDOMINAL HÆMATOCELE.

By Surgeon-Major W. GRAY, I.M.D.,

Senior Surgeon, Jarnsetjee Jejeebhoy Hospital, Bombay.

Essub E—, aged thirty-six, a cart driver, was admitted to the Jarnsetjee Jejeebhoy Hospital on March 6th last, suffering from great enlargement of the right side of the scrotum, and also from what appeared at first sight a distended bladder. The latter belief was strengthened by the fact that there had previously been some difficulty in micturition, and by the additional circumstance that the house-surgeon, on attempting to withdraw the urine, found it impossible to pass even the smallest catheter beyond the bulb. The history, so far as it could be ascertained, was that about a year ago the scrotum began to swell, and gradually attained its present size. A month before admission he first noticed the hypogastric tumour, and it was in consequence of the rapid enlargement of this during the last few days, and the increasing pain and discomfort which it caused, that he came to hospital for relief. The patient was unable to furnish any data that could throw light on the origin of the disease. All he could tell us was that up to a year ago he was in perfect health, and had nothing whatever the matter with either the scrotum or cord. Urine had always been passed freely until lately. He was emaciated and anæmic, passed urine with difficulty and in a narrow twisted stream, and complained of considerable pain and tension in both swellings. There was no history of injury. The scrotal tumour was cylindrical in shape, about six inches in diameter, and when the patient stood up it descended nearly to the knee. The hypogastric tumour looked and felt, as the patient lay on his back, almost exactly

like a case of retention of urine; it reached a little above the umbilicus.

On making a careful and detailed examination the day after admission, when I first saw him, it was noted that both tumours contained fluid, and that they communicated freely with each other. Placing one hand at the bottom of the scrotal tumour, and percussing the hypogastric swelling with the fingers of the other, a distinct wave of fluid was felt to pass. According to the position, too, either tumour could be considerably increased in size at the expense of the other. When he stood up the scrotum filled out, and the abdomen became less prominent; the reverse happened if the scrotum was elevated while he lay on his back. Coughing also made the scrotum swell up. Except this impulse, no evidence of hernia could be detected, either by local examination or from the history. The precise nature of the case was now the question to decide. Standing in front of the patient it was noticed that the hypogastric tumour was in the very slightest degree larger on the right side of the middle line. In fact, the difference was so small as not to be perceptible unless carefully looked for. This fact alone seemed sufficient to cast doubt on the distended bladder theory. Closer examination of the urethra and perineum showed that the obstruction to the passage of urine was due to the pressure of the upper part of the scrotal tumour on the urethra, and on further cross-questioning the patient it appeared that he had been passing, though with difficulty, the normal quantity of urine daily.

It now became sufficiently clear that the case was one of hydrocele or hæmatocele, presumably the latter, which had extended upwards along the cord and under the crural arch, and finally formed a second sac for itself within the abdominal cavity. A small exploring trocar soon showed that the tumour was filled with fluid blood, and a larger trocar and cannula having been inserted, nearly five pints of this were drawn off, and both tumours completely emptied. A large syringe of 5 per cent. carbolic acid lotion was then injected, the trocar wound carefully closed, and an ice-bag placed over the cord. There was now no difficulty in passing a catheter and removing from the bladder a small quantity of bloody urine. A noticeable circumstance was that the fluid drawn from the tumours possessed a distinctly urinous odor. This fact induces me to think that at one period or other of the case there may have been a communication between some portion of the bladder and the upper sac. Unfortunately, through some misapprehension, the fluid was not examined for evidence of the presence of urine. The blood in the urine withdrawn by the catheter was probably due to the attempts made to relieve the supposed retention: there was no blood noticed afterwards.

By the third or fourth day after the operation it was evident that the tumours were rapidly refilling. Early on the morning of the 12th the patient was found in a state of semi-collapse, with both tumours larger and tenser than ever. Percussion revealed the fact that they were tympanitic, and the hasty conclusion was formed that a hernia had descended, and had become strangulated. More careful examination, however, showed a drop of fetid matter oozing from the trocar wound, when it became at once apparent that the tympanitic note was due, not to intestinal flatus, but to the gases of putrefaction. The patient was immediately placed on the operating-table, chloroform administered with extra precautions, and the scrotal tumour then laid open from one end to the other. A quantity of decomposed blood-clot and fetid matter was turned out, the interior of both cavities thoroughly

cleansed with carbolic lotion, and a large drainage-tube was placed in the abdominal sac, with its end hanging out through the scrotal incision. The patient was then removed to bed, and appropriate general and local treatment administered. For some days he remained in a very precarious condition, but eventually rallied, and was able some time later to undergo a second and final operation. The walls of the scrotal sac were fully a quarter of an inch in thickness, and were composed of tough fibrous tissue. Its inner surface was rough, and in general appearance was not unlike the mucous membrane of the stomach in a case of arsenic-poisoning; in color it was dark purple. The opening of communication under the crural arch, between the two portions of the sac, was wide enough to admit four fingers or a small hand, and the interior surface of the abdominal sac was felt to be similar to that of the scrotal sac. The source of the hæmorrhage was sought for in vain.

The patient having regained strength, and the parts looking sufficiently healthy, he was, on March 28th, again placed under chloroform, and the redundant portion of the scrotal integument, together with the whole of the sac wall below Poupart's ligament, were excised. As the testicle had atrophied to a mere nodule, it also was removed. The wound was then closed with silver sutures, the drainage-tube of the abdominal sac being brought out at its upper angle. From this time the patient made an uninterrupted recovery; the scrotal wound healed readily, while the upper cavity, which for a time discharged freely, gradually contracted, and by degrees pushed out the drainage-tube. He was discharged well on May 12th, returning to his former avocation of cart driver. I have since had an opportunity of seeing him. The scrotum is of natural size, while the abdominal sac is apparently obliterated, and the sinus quite closed.

I think this case is worthy of publication, both from its rarity and on account of the success of the treatment adopted. I have never seen or heard of a similar case in this country, where hydrocele and hæmatocele are so common. Professor G. M. Humphry mentions a case of "abdominal" hydrocele in his article in the "System of Surgery."¹ Nothing further has been added to this by Mr. Jacobson in the third edition. J. Rochard records an instance of "abdominal" hæmatocele complicated with hernia.² Beyond these cases I can find no reference to the subject. The liability, after a cursory examination only, to mistake the present case for one of retention of urine was natural enough, and forms an interesting feature of it. As regards the origin of the abdominal sac, the very unsatisfactory history of the double tumour leaves us more or less in the dark. In the absence of any better explanation I am content to accept that offered by Professor Humphry—namely, the persistence, unclosed except at its upper part, of the funicular portion of the peritoneal pouch which accompanied the testicle in its descent. The gradual distension of the scrotal sac caused the canal to yield where it passed through the abdominal wall, and finally to dilate into a large pouch behind. The patient, however, adhered to his original statement, that up to a year before his admission to hospital he had no swelling of either the scrotum or cord, nor had he sustained any injury of the parts. Still, long experience has taught us that the histories of their diseases given by our hospital patients are, as a rule, more or less incomplete or untrustworthy.

¹ Vol. v., p. 85, second edition.

² Mentioned in the Sydenham Society's Year-book of Medicine and Surgery for 1861, p. 312.

I shall be glad to learn whether readers of *THE LANCET* have met with cases at all similar to this, and if so, whether they can throw any further light on its mode of origin and progress.

Bombay.

ON A CASE OF POISONING WITH BICHROMATE OF POTASH.

By EDWARD ORR MACNIVEN, M.B., C.M. Ed.,
House-Physician in the Glasgow Royal Infirmary.

B. D—, twenty-two years of age, a workman in Mr. Carlyle's chrome works, was admitted under Dr. Maclaren in the Glasgow Royal Infirmary on Dec. 10th, 1882, suffering from the effects of swallowing a quantity of bichromate of potash.

History.—The patient, a fairly muscular man, in a fit of jealousy went to the chrome works about five o'clock on Sunday evening and swallowed a lump of chrome (the purified salt) in the solid form. He then returned to his lodging, which is about fifteen minutes' walk from the works. As soon as he reached his room he experienced the following symptoms:—The first thing he noticed was a lightness in the head, then a sensation of great heat in the stomach, with a glow of heat all over the body, and this was followed by a cold sweat. Next he became sick, and vomited freely. He then suffered from agonizing pain in the epigastric region, with giddiness, specks before the eyes, and loss of power of the legs. (He had complete power of his arms.) His thirst was intense; and he aptly expressed himself, "that he felt as if he could drink the sea dry." Lastly, he complained of severe rigors, with coldness of the whole body, more especially of the extremities.

The patient was carried into the hospital at ten minutes to seven o'clock (nearly two hours after swallowing the poison), and on examination I found the pupils slightly dilated, the face pale and extremely cold, and the pulse feeble and fluttering. There was no vomiting then; but he complained of intense pain over the region of the stomach, and a feeling of great depression. No cramps or diarrhoea were present. There was a degree of stupor, but he answered questions fairly well. Sensibility to touch and pain was well marked.

Treatment.—This consisted in giving a full dose of sulphate of zinc, and washing out the stomach with tepid water by means of the stomach-pump till the fluid was colorless. As the pulse threatened to fail, I injected subcutaneously twenty minims of sulphuric ether, which was followed by a marked improvement. The patient was covered with plenty of warm blankets, and hot bottles were applied to the feet and sides. A mustard poultice was applied over the stomach, which gave great relief. I next tried the administration of some tepid coffee well diluted with milk and plenty of brown sugar. This was rejected at once; but some milk well mixed with a good quantity of lime water and ten grains of subnitrate of bismuth were retained. Barley water was given as a drink, and the patient was ordered milk diet with lime-water. He slept fairly well that night, and in the morning every symptom had disappeared, except a slight soreness of the mouth. Diet was strictly attended to as usual. The patient made a perfect recovery without a single bad symptom.

Remarks.—(1) The first symptom—viz., the lightness in the head, apparently a tendency to syncope—took place fifteen minutes after he had swallowed the poison. (2) Had it not been that vomiting occurred in his lodgings, which happened about twenty minutes after he had taken the poison, and that the patient had taken food

about an hour and a half before he entered the works, the effects might have been much more disastrous. (3) Although a good quantity of the poison was found in his stomach, yet the rapid evacuation of its contents, together with the application of tepid water, along with milk, lime-water, and bismuth, tended to soothe the mucous membrane and diminish the chance of inflammatory action. The application of the mustard externally had also a beneficial effect in the same direction. (4) Over two drachms, according to the patient's account, must have been swallowed, and, by a rough analysis of the stomach's contents, I estimated that it contained nearly one drachm of the bichromate. (I made the patient select a piece of the bichromate, which he thought was exactly the same size as that which he swallowed, and then I weighed it, and found it over two drachms.) No trace of the poison was found in the urine with the ordinary tests for its detection—viz., nitrate of silver = red, acetate of lead = yellow, H_2S = dingy green.

As bichromate of potash poisoning is of somewhat rare occurrence, perhaps a brief summary of the leading symptoms of a few cases recently recorded, comparing these with those of the case just described, might be interesting.

CASE 1 (recorded by Dr. McLachlan).¹—Accidental poisoning, in which three drachms were taken dissolved in water, and the first symptom appeared a quarter of an hour after administration:—Symptoms: Excessive vomiting, purging, violent abdominal pains, with cramps in the legs; coldness of the surface of the body. Hands shrivelled, wrinkled, and dusky, like a person in the advanced stage of cholera; face and lips dusky, with yellowness of the conjunctivæ; excessive thirst, feebleness of the pulse, hurried respiration; suppression of the urine; soreness of the mouth; mental faculties unimpaired. Resembling the case I have described in having the following symptoms: Vomiting; abdominal pains; excessive thirst; coldness of the surface of the body; feebleness of the pulse; soreness of the mouth. Differs from it in (1) the following symptoms being absent: Tendency to syncope, with giddiness; specks before the eyes, with slight dilatation of the pupils; degree of stupor; loss of power of the legs; and in (2) the following symptoms being present: Suppression of urine; purging; hurried respiration; peculiar condition of the face and hands, with yellowness of the conjunctivæ.

CASE 2 (recorded by Dr. R. Archer Warwick).²—Intentional poisoning, in which a lump of chrome about half an ounce in weight was taken, and the first symptom appeared in one or two minutes after administration:—Symptoms resembling the case I have described: Pain in the stomach and back; giddiness and vomiting; with violent retching; loss of power of the legs; feebleness of the pulse, and clammy perspiration. Differing from it: Purging, with blood in the stools.

CASE 3 (recorded by Dr. McCrorie).³—Symptoms resembling: Vomiting; dilatation of the pupils; feebleness of the pulse; tenderness of the abdomen; coldness of the surface of the body, with clammy perspiration. Differing: Purging; difficult, wheezing respiration.

CASE 4 (recorded by Dr. Dunbar Walker).⁴—Accidental poisoning in which one drachm was taken dissolved in water, and the first symptom appeared in five minutes after administration. Symptoms resembling: Sickness; tendency to syncope; coldness of the body; pain in the abdomen; feebleness of the pulse. Differing: Purging.

¹ Glasgow Medical Journal, July, 1881, p. 31.

² Glasgow Medical Journal, May, 1881, p. 378.

Judging, therefore, from the cases just mentioned, and from those of an earlier date,³ the symptoms produced with bichromate of potash are those of an irritant poison, and may be described as follows:—

1. General or usual symptoms: Abdominal pains; vomiting; purging; cramps in the legs; feebleness of the pulse; coldness of the surface of the body, with clammy perspiration; soreness of the mouth and throat and excessive thirst. 2. Remote symptoms: Tendency to syncope, with giddiness; specks before the eyes, dilatation of the pupils, and yellowness of the conjunctivæ; suppression of urine; stupor; hurried or difficult respiration; loss of power of the legs.

The accurate experiments on dogs with this substance, performed by Professor Gmelin, of Tübingen,⁴ are also worthy of note, as illustrating the valuable information to be derived from such investigations.

Lastly, the local effects on workmen who use the bichromate of potash in dyeing, as described by Drs. Duncan⁵ and Eadie⁶, of Glasgow, are of great practical interest, and illustrate the caustic action of this poison. It seems that on those workmen who have the slightest abrasion of the skin the poison acts as a caustic, producing a tough slough, followed by an ulcer with hardened cup-like border. These sores may gradually extend deeper and deeper, until they eat their way into the bone, and sometimes they actually make their way through the arm or hand altogether. Attacks of conjunctivitis are also of not uncommon occurrence. These observations I can fully confirm.

Glasgow.

CASE OF CYSTIC TUMOUR OF LEFT OVARY EXISTING DURING SEVERAL PREGNANCIES.

REMOVAL OF BOTH OVARIES, WITH RECOVERY.

By A. C. BUTLER-SMYTHE, M.R.C.P., F.R.C.S. Ed.

Surgeon to the Farringdon General Dispensary and to the Hospital for Women, Vincent-Square.

Mrs. W—, aged thirty-three, married fifteen years, has had eight children (one premature at the end of the seventh month) and two abortions. The catamenia appeared at the age of thirteen, and up to the year 1877 she had always had good health. There is no history of tumour in her family. She states that five years ago, when about seven months gone with her seventh child, she was coming out of the Victoria station and slipped on some orange-peel and fell, striking the left side of her abdomen against the kerb. She was stunned for a few moments, but recovered, and afterwards went her full time and had a fairly good labour. Some days after her confinement, however, she had an attack of what her medical attendant termed "inflammation of the womb," which laid her up for three weeks. Two months subsequently she had rheumatic fever, and kept her bed for seven weeks. About a year after the fall, when three months advanced in her eighth pregnancy, she noticed on her left side a perfectly movable swelling the size of an orange, and complained of a dragging pain in that side. She aborted at the fifth month, and was attended by a midwife, the abortion being fol-

lowed by another severe attack of "inflammation." Two and a half years ago she completed her ninth pregnancy, and had a lingering labour. After her delivery her medical attendant found a large swelling in the left side, and diagnosed "an abdominal tumour of doubtful nature." She was told to go to some hospital for further advice, and attended for seventeen months as an out-patient at different London hospitals, but the abdominal condition seems to have been overlooked. In April last, when three months gone in her tenth pregnancy, the pain in her left side became so bad that she fainted on several occasions, and at last took to her bed. During the next four months her sufferings increased to such an extent that she could not lie down in any position, but had to be propped up in bed, or in a chair, in order to procure sleep. She was prematurely confined of a living child at the middle of the seventh month, after a painful and tedious labour extending over two days. Her confinement was followed by increased pain in the left side, which continued to within a week of the operation. She tells me, and her statement is confirmed by her medical attendant, that in her last two pregnancies the child lay in the right side, but more particularly so in the last, when the womb was pushed completely to the right of the navel; and after delivery a distinct hollow could be felt and seen on the right side, whilst the swelling in the left remained almost unaltered. After her last confinement, the tumour began to grow rapidly, and she lost much flesh. Her appetite failed, and her spirits became depressed. Menorrhagia and metrorrhagia were frequent symptoms, and she complained of pressure over the bladder, with difficulty in micturition. The constant pain and loss of sleep had reduced her to such an extent that walking was out of the question, and the slightest exertion produced giddiness and faintness. I first saw her in January, 1883. She was then pale and much emaciated, her features were drawn and pinched, and she seemed too feeble to stand. She complained of a constant dragging and tearing pain in her left side, which prevented her lying down, and kept her awake at night. Further examination showed her abdomen to be irregularly enlarged, and very tender. There was dullness over the front, and resonance in the flanks. Fluctuation could be detected in parts, and aortic impulse was perceptible. The tumour was movable, and seemed pretty solid. On vaginal examination the uterus was found to be enlarged and anteverted, the os was patulous, and the sound passed two inches and a half. The diagnosis was "a multilocular tumour of the left ovary with little fluid." The patient being in such a wretched state of health, I determined to wait till after her next period, and put her on a course of iron, and gave her carbonate of lithia in five grain doses three times a day, to correct the urine, which was thick and loaded with urates. She rapidly improved under this treatment, but the tumour gained in size. Accordingly, on Feb. 6th, 1883, I performed ovariectomy.

The patient being chloroformed, I opened the abdomen under carbolic spray, and found the tumour free from adhesions on the right side, but on the left there were several long thin bands stretching from the abdominal wall, and in front a portion of the intestine had become attached to the tumour by a thin band which required ligaturing. The contents of the tumour being too thick to pass through the trocar, it was withdrawn, and introducing my hand, I broke down several secondary cysts, but in the end had to enlarge the incision before the mass could be extracted. The right ovary, being enlarged and cystic was also removed, and the peritoneal cavity well sponged

⁶ Guy's Forensic Medicine, p. 510.

out. The wound was closed with carbolized silk ligatures and dressed with antiseptic gauze. The tumour weighed over twelve pounds.

The patient made a good recovery. On the third day she passed her water voluntarily, and both pulse and temperature were normal. On the seventh the sutures were removed, when the wound was found to be quite closed. On the eleventh day the bowels acted, and before the end of the third week she was up and able to walk. She is now in good health and has resumed her duties at home.

Remarks.—This case seems to me interesting because it shows that during the development of an ovarian tumour several pregnancies may occur, and end in the birth of living children and in the safety of the mother. The history of injury to the left side seems worthy of some notice, since the patient dates all her troubles from the accident, and further adds that she has never been free from pain in her left side since the time of injury. Considering the number of pregnancies and the history of pain, together with the general condition of the patient before the operation, I was rather surprised at the small amount of adhesions met with in this case. The spray apparatus stopped working just before the wound was closed, and I had to finish without it. In all other respects antiseptic precautions were taken during the operation.

Brook-street, W.

CONGENITAL UMBILICAL HERNIA.

By C. W. ROBINSON, M.R.C.S., L.S.A., etc.,

Honorary Surgeon to the North Shields and Tynemouth Dispensary.

THOUGH umbilical hernia is nothing but a common disease, the congenital form is of very rare occurrence, and operations for the same are still less frequent. The case which I wish to place on record is of the utmost interest in more points than one. First, its great size; secondly, its external appearance; thirdly, the morbid condition of the abdominal viscera, with other minor points.

On the morning of Jan. 16th, 1883, at 3 A.M. Mrs. D— gave birth to a female child at full time, to all appearance perfectly healthy, with the exception of the presence of an umbilical hernia of unusual dimensions; the size of the tumour slightly exceeded that of the child's head, which was fully developed. At the junction of the tumour with the abdomen a well-marked constriction was noticeable; the contour of the tumour was even and regular, describing the better half of a hemisphere; it was soft, fluctuating, and tympanitic. It was not difficult to be certain of its contents, because a portion of the front of the hernia, about two inches in diameter, was perfectly transparent, and this transparent portion, which formed what might be called a false covering, was composed of a part of the umbilical cord covering, having evidently expanded under pressure, and was simply, as might be anticipated, in continuity with the integument of the abdomen. The appearance was extremely curious; nearly the whole of the small bowel was distinctly discernible, and its peristaltic action seen very perfectly. There was no approach at strangulation; and on an attempt being made at reduction, nearly the whole of the contents of the tumour were returned into the cavity of the abdomen, leaving plenty of loose integument over the site of the hernia—a fact worthy of note, as upon this point rested principally the chances of a

successful operation, which, on being proposed to the parents, was readily assented to.

The grounds on which I based my opinion for surgical interference were:—1. The apparently perfectly healthy condition of the child. 2. The certainty of a rupture of the transparent and exceedingly thin integument covering the front of the tumour at an early date. 3. There being plenty of loose integument after a reduction was effected left no grounds for hesitation on that score. After a consultation I fixed the operation for 5 P.M. of the same day, as there was clearly no time to be lost, and there was no other alternative left. The operation consisted in making an elliptical incision just a quarter of an inch outside the transparent portion, first making an incision through the skin; then after a little careful dissection coming down to the peritoneum, which I pinched up with a pair of ordinary dissecting forceps, and cut through into the cavity of the abdomen; next, with a director and an ordinary hernia bistoury I completed the incisions, whereby the elliptical portion of integument above mentioned was removed. When on careful examination of the viscera all hope of a successful issue of the operation was nearly at an end (the liver was intensely congested, and a portion of the intestine, which had not been seen before, was in a gangrenous condition, but not in an advanced stage), I deemed it advisable to return the bowel, which had partially escaped from the wound, to await the result, whether favorable or otherwise. I may mention here that chloroform was administered very carefully by a brother practitioner. This being done, I closed the wound by a continuous suture, and, having dressed the wound with oiled lint, applied a bandage. The little patient died within two hours of the operation. Unfortunately the friends would not allow a necropsy, and the exact cause of the morbid appearances can only be arrived at very imperfectly. It seems a curious circumstance that during the few hours of the patient's existence no external signs, either subjective or objective, were observable. The hæmorrhage was very limited in extent.

Tynemouth.

INVESTIGATIONS RELATIVE TO INHALATION AND DISINFECTION.

WITH DESCRIPTIONS OF NEW FORMS OF APPARATUS.

By ARTHUR HILL HASSALL, M.D. Lond.,

Late Senior Physician to the Royal Free Hospital; Founder of and Consulting Physician to the Royal National Hospital for Consumption and Diseases of the Chest on the Separate System.

In my paper published in *THE LANCET* some months since I stated the results of certain experiments made with some of the principal of the oral and oro-nasal inhalers now in use, and I showed that after the completion of one and even two hours' inhalation more than four-fifths of the antiseptic substances usually employed, as carbolic acid, creasote, and thymol, were recoverable from the sponge or cotton-wool of the inhaler. I pointed out that there were several ways in which the small loss which had taken place might in part be accounted for, without its being supposed that the antiseptics had really made their way to the seat of the disease in the lungs themselves. I have since continued my investigations and made many further experiments bearing on the subject of inhalation. In a paper communicated to the British Medical Association at its recent meeting at Liverpool, I gave the results derived from certain trials and experiments made with some of the chief air and steam sprays, and I showed that

in the case of the sprays also a very large proportion of the antiseptics employed were recoverable; the inference being that, except in the case of throat affections, they were but little more effective than are the oro-nasal and oral inhalers, as at present constructed and used. In the same communication I detailed the results of experiments with an apparatus devised in imitation of natural respiration; these proved that, using the oral and oro-nasal inhalers and the air and steam sprays as at present practiced, not more than traces of the antiseptics used made their way into and were to be detected in the water or spirit contained in the receiver, or Woulfe's bottle, placed at the end of the trachea of a recently killed sheep.

Recognizing the inefficiency of the means now resorted to, for introducing into the lungs various antiseptic and other curative substances by means of inhalation, I was led to consider whether it were not possible to charge the air of a chamber with the required medicaments, and these in the proper amounts, and I have communicated my observations and experiments under this head to the British Medical Association in a second paper.

Without entering into details, I may here state that I have arrived at the conclusion that such a charging of the air of chambers is really practicable, an object which has not, so far as I am aware, been hitherto accomplished. For effecting this purpose I rely on two principles: one is the greatly increased volatilization of certain chemical substances, which at the ordinary temperature of the air are but little volatile, obtained by spreading the substances over a very considerable surface, and exposing them either in the air or on water. To show the effect of this principle, I may mention that 50 grammes, or 770 grains, of carbolic acid, exposed to the air on a rough and moistened fabric, having a superficies of eight square feet, had disappeared, and were entirely lost at the end of thirty hours. Now, had the same quantity of the acid been exposed to the air in any vessel presenting only a small surface, the loss would have been but trifling, and in fact the weight of the crystalline acid would have become increased by the formation of the liquid hydrate. The second principle is the augmented evaporation obtained by increase of temperature in combination with extension of surface. Armed with these two principles, applied in a practical manner, we possess the means, as I have said, of charging chambers with medicaments to any required extent, and of forming true inhalation chambers. The second paper already referred to, dealt mainly with the principles of the construction of inhalation chambers, and did not enter into any definite description of the means to be employed; these details were left for further observation and inquiry.

I now proceed to give the necessary data on which the methods to be used are based, and to describe the apparatus I have devised. A piece of Turkish towel 16 by 11 inches, giving a superficies on the two surfaces of 352 inches, was moistened with 100 cubic centimetres of water, containing 100 grains of carbolic acid. Six of such pieces were similarly treated, suspended on glass rods, and the amount of carbolic acid contained in them determined at the end of each successive hour; the quantities recovered were 82.79, 75.49, 63.89, 57.02, 48.73, and 41.39 per cent. These figures show a progressive loss each hour of 17.21, 24.61, 36.11, 42.98, 51.27, and 58.61 per cent. Thus, if the six pieces had all remained suspended for the six hours, of the 600 grains of carbolic acid used in charging them, no less than 350 grains would have disappeared, or more than one half. Six

cloths of the same dimensions were next taken, each being moistened with a mixture of spirit and water in equal parts, containing 120 grains of creasote; the entire quantity in this case for the six cloths would therefore be 720 grains. There were recovered at the end of each successive hour the following amounts: 103.5, 86.8, 83.7, 80.8, 72.0, and 66.0, showing a loss of 16.5, 33.2, 36.3, 40.0, 48.0, and 54.0. Thus, of the 720 grains taken, no less than 324 grains would have disappeared had all the cloths been suspended for the six hours. Lastly, five cloths were each moistened with a mixture of spirits of wine and water, in equal parts, containing 5 grammes of thymol, = 77 grains; these cloths therefore contained 25 grammes of thymol, or 385 grains. The following amounts were recovered each hour: 4.74, 4.44, 4.08, 3.88, 3.12 grammes, = 73.0, 68.3, 62.8, 59.7, and 48.0 grains respectively, the loss for each cloth in grains standing thus: 4.15, 8.78, 14.30, 17.4, and 29.15 respectively.

Here, again, the loss is very considerable, although not so great as in the two previous cases. Had all the cloths been exposed the whole time, the loss would have amounted to 145 grains out of the 385 originally taken. A considerable loss, of course, also takes place in the case of other but little volatile substances, exposed in the same manner on an extended surface, dissolved, if necessary, in suitable menstrua, the extent of the loss being proportionate to the natural volatility of the substance and its solubility. If the loss is so great resulting from the exposure of such a limited superficies as is afforded by a suitable fabric of 16 by 11 in., it is obvious that by extending the surface we possess a most powerful means for charging the air of a chamber with any required medicament, although it may possess only a feeble volatility at ordinary temperatures, and this to any extent required. But there is still another means whereby the same result may be aided or accomplished—namely, by exposing the substances on a comparatively extended surface of water, or even by dissolving them in it, raising and maintaining in some cases the temperature of the water at certain fixed degrees.

The following figures will serve to show the results obtained by this proceeding. Two grammes and a half of carbolic acid were dissolved in 150 cubic centimetres of water, and placed in a small glass dish having a superficies of eight inches; five other dishes were similarly charged, and all were floated on a water-bath, the temperature of the liquid in the dishes being maintained at about 74° C., or 165° F. And here I would remark that the temperature should always be taken of the liquid in the dishes themselves, and not in water in the outer bath, as there is often a difference of 6° to 8° between the two, according to the nature of the vessels employed. The quantity of carbolic acid therefore contained in the six dishes amounted to 15 grammes, or 231 grains. The amounts recovered were 1.838, 1.470, 1.116, 0.868, 0.661, and 0.511 = 28.3, 22.6, 17.2, 13.3, 10.1, and 7.8 grains respectively. It thus appears that of the 38.5 grains originally present only 7.8 grains remained at end of the six hours. It follows therefore that of the 231 grains originally taken all but 47 grains would have been dissipated had all the dishes been exposed for the same length of time equivalent to more than three-fourths. With similar quantities of creasote—namely, 2.5 grammes—for each dish the results stand as follows:—In the first experiments the creasote was allowed to remain at rest, the greater part sinking to the bottom, it being only partially soluble in water, and part floating on the surface. There were recovered successively 1.245, 0.894, 1.10, 0.51, 0.21, and 0.37 grammes, = 19.17, 13.76, 16.94, 7.85,

3.23, and 5.69 grains. Thus, in this case had the temperature of all the dishes been maintained for the six hours, no less than 197 grains would have disappeared out of the 231 grains originally taken.

When, however, the contents of the dishes were stirred occasionally with a glass rod, whereby the heavier portions of the creasote, which had fallen to the bottom of the dishes, became broken up and dispersed, the loss was still more considerable, as indicated by the following figures:—0.76, 0.62, 0.43, 0.13, 0.035, 0.00, — 11.70, 9.54, 6.62, 2.00, 0.54 grains, while from the last dish the whole of the creasote had disappeared. The experiments with thymol furnished results almost equally striking. This substance is soluble only to a trifling extent in water, and when exposed to the air at ordinary temperatures, although it gives off its pleasant smell freely, it scarcely loses weight at all; thus 15 grammes exposed to the air were found to have lost only the most trifling amount at the end of a fortnight. But thymol melts rapidly in hot water, and, being lighter than water, floats upon and spreads over its surface in a thin scum, and in this condition it becomes rapidly volatilized, as will be apparent on an examination of the annexed figures. 2.5 grammes being added to each of the six dishes containing the usual amount of water, the temperature of which was maintained at 74° C., the following amounts were recovered:—1.82, 1.23, 0.874, 0.64, 0.36, 0.096 grammes = 28.02, 18.94, 13.46, 9.85, 5.54, and 1.47 grains. Thus, had the experiments been continued with all the dishes for six hours, the loss would have amounted to 123 grains out of 131 taken at the commencement.

Armed with these principles and data I have been led to devise the following forms of apparatus, the first two being intended for charging the air of chambers for inhalation and disinfection. The first of these, which I have named the "chamber inhaler and disinfector, No. 1," consists of a long fabric woven so as to afford a very large extent of surface for evaporation. The length and breadth of this vary with the extent of the effect required to be produced. This is spread out in several tiers one above the other, by means of an arrangement consisting of a double series of rails which are attached to a box, and which lift out and in. These, when not in use, are packed away in the box, which also contains a tray to catch any drippings, and a tin box to receive the long cloth.

A second apparatus, the "chamber inhaler and disinfector, No. 2," consists of an outer water-bath to which a thermometer is attached, and an inner porcelain dish divided into four equal parts. The divisions of this are also filled with water, the temperature of which, by means of the outer bath, can be regulated and maintained to a nicety. With this apparatus, if desired, no less than four antiseptic or other substances may be used at the same time, either for inhalation or disinfection. It combines the advantages of moderate extent of surface with a temperature augmented, but regulated according to the nature and composition of the substances used—a very valuable combination. No hospital should be without one or more of these powerful disinfectors, especially the No. 1 "chamber inhaler and disinfector." It will also be found of great service in private houses in cases of infectious disease. In using them one important fact must be borne in mind—namely, that it is not possible to charge the air of any ward or room with any medicinal substance or disinfectant while the doors and windows are open, as of course any amount of the substances which may be eliminated will be too rapidly dispersed to be of any service. It is not possible

therefore to combine either effective inhalation or disinfection with free ventilation.

It occurred to me that some, at all events, of the advantages gained by increasing the surface of exposure might be obtained by applying the principle of extension to the construction of oro-nasal and oral inhalers, and with this object I made a variety of experiments. Without giving in detail the results of these I will now describe two inhalers I have devised, the "globe" oro-nasal inhaler, and the "globe" oral inhaler.

That the inhalers at present employed are defective in construction in many ways, and are all but useless in practice, particularly in chest affections, has, I think, been sufficiently demonstrated. One defect is that, as a rule, they are not accurately adapted to the contour of the face of the wearer, so that air enters freely through other than the proper channels. Another is that the amount of the substances used is generally much too small, and this is also the case with the materials on which these are placed; then the nature as well as the size of the materials selected, such as sponge or cotton-wool, are but ill-suited to the object in view, since they hold but a few drops of liquid and even these are sufficient so to clog them as to render them more or less impermeable to the air, which should pass in all directions freely through them. In fact, the physics of the right construction of oro-nasal and oral inhalers have been even less studied than has the chemistry of the substances employed. The "globe" oro-nasal inhaler consists of a covering for the nose and mouth of a material which, becoming flexible in hot water, may be accurately adapted after it is made to the contour of the face of the wearer—a point of great importance with all oro-nasal inhalers. To this is attached a light glass globe, which is filled with a suitable material packed so lightly as to allow of its ready permeation by the air drawn through it in inspiration. This is then charged with the medicines desired to be employed. Supposing carbolic acid to be used, the quantity would be from 1½ to 2½ grammes, = 23.14 and 38.57 grains, partially dissolved in 8 c.c. of water, = 2 drachms. The extent of the loss of this antiseptic varies according to the amount of the acid taken, the care with which the globe is charged, the greater or less vigor with which the act of inspiration is carried on, and the length of time occupied in the inhalation. When 2½ grammes are used and the inhalation continued for two hours the loss varies from half to one gramme, or 15.4 grains.

Although I have repeatedly used my "globe" oro-nasal inhaler with a charge of 2½ grammes of carbolic acid and have inhaled for two hours at a time, I have never experienced any decidedly ill effects, still I would recommend that the quantity used to begin with should not exceed 1½ gramme. The Pharmacopœial dose of carbolic acid for internal administration is one grain only. What portion of the amount of the antiseptic which disappears actually makes its way into the lungs has yet to be determined, but there is no question that, with my apparatus, much of it does really enter the system, part of it being absorbed by the mucous membrane of the mouth and fauces. A little, no doubt, is lost on the skin, and when a mustache or beard is worn upon it as well. While using this inhaler the carbolic acid may be strongly smelt and tasted, and in a short time the skin of the lips becomes whitened and a tingling sensation may even be experienced in them; these last effects are produced wholly by evaporation, as, although the quantity of water or other menstruum used is several times larger than that employed in ordinary inhalers, not a drop ever escapes

from the inhaler to the mouth, as so often occurs with most other oro-nasal inhalers. The last apparatus, the "globe" oral inhaler, consists of a glass globe with, on the distal side, an aperture and a cribriform plate for the entrance of the air during inspiration, and on the near side a flattened tube for the mouth, guarded by a valve, which prevents the air being discharged into the globe during expiration. The nose is uncovered, the flattened tube only enters the mouth, and the air is drawn through the globe in the same manner as through a cigar or pipe. By the use of this inhaler, the objection so often urged against oro-nasal inhalers is removed: that by covering the nose and mouth they restrict the entrance of the air and greatly impede respiration; moreover, its employment is far less irksome and fatiguing; it may be taken up or put down in a moment, and when once charged it may be used for one or two days, in most cases without requiring to be refilled. The ordinary quantities of carbolic acid for this inhaler are the same as those for the "globe" oro-nasal inhaler. All persons do not use oro-nasal inhalers alike; some inhale simply by the nostrils and close the mouth during inhalation, others inhale by both the nose and mouth, and this is the best way since the mouth being open, a portion at least of the medicaments used make their way directly to the throat without having to take the longer and more tortuous course, with the inevitable result of part of the substances becoming absorbed. The "globe" oral inhaler has therefore a distinct advantage over the "globe" oro-nasal inhaler in that the whole of the medicaments pass at once into the mouth, none being lost on the skin of the face and lips, on the mustache or beard, or in the convolutions of the nares.

I have communicated all the necessary particulars to Mr. Banks, of the firm of Messrs. Maw, Son & Thompson, respecting the four different kinds of apparatus above described, and he is now having them constructed. The firm will therefore, I hope, be prepared to supply them very shortly.

San Remo.

NOTES OF A CASE OF UTERINE FIBROID REMOVED BY ABDOMINAL SECTION.

PEDICLE TREATED WITH SILK; HÆMORRHAGE IN TWELVE HOURS; REOPENING OF ABDOMEN, AND APPLICATION OF KOEBERLE'S SERRE-NEUD; RECOVERY.

By J. CRAWFORD RENTON, M.D. Edin.,

Surgeon to the Dispensary of the Western Infirmary; Surgeon to the Eye Infirmary, Glasgow.

Mrs. A—, aged thirty-five, married, no family, was sent to me in October, 1882, by Dr. Allan. She complained of a swelling in her abdomen, which she stated had existed for ten years; recently it had grown somewhat, and had given her pain and inconvenience, so that she was anxious to have it removed if possible. On Nov. 10th she was admitted to the Training Home for Nurses. On examination per hypogastrium, a round doughy tumour was found, movable, with obscure fluctuation; measurement round umbilicus thirty-two inches. Per vaginam: The uterus is high up in the pelvis, but movable, and seems to move along with the tumour; probe passes easily. Per rectum: The tumour is felt passing into Douglas' space; menstruation regular. Had not had attacks of menorrhagia. Dr. Allan and Dr. Beatson examined the patient with me, and we were of opinion that we had probably to deal with a uterine outgrowth closely attached to the uterus. The

woman was otherwise in good health and with no history of serious peritoneal pains, and as the mass gave rise to great discomfort we recommended her to have it removed.

On Nov. 18th, assisted by Drs. Allan, Beatson, and Nairn, I performed the following operation. An abdominal incision, four inches in length in the median line, was made, and the surface of the tumour exposed. No adhesions were found except one or two at the right side; a trocar was passed into the growth, and as only a little blood escaped, it was evident that we had to deal with a solid tumour. The abdominal opening was enlarged two inches upwards and downwards, and the tumour was found growing from the uterus and attached by a distinct pedicle, which was six inches in circumference and two and a half in thickness. The tumour was turned out and a Foulis's band, fitted with hooks instead of the ordinary catch, was applied to the pedicle. This controlled the large vessels in it; and on Dr. Beatson's suggestion I passed a skewer through the pedicle above the band and then cut off the tumour with the ovaries attached. I now secured the pedicle with four strong Keith's silk ligatures below the band, and having done so I removed it and cut off with the cautery an inch and a half of the pedicle, which was now dropped into the abdominal cavity, the wound closed with silk sutures, dressings applied, and the patient placed in bed. The operation lasted an hour and twenty minutes from the commencement of chloroform inhalation to the time the patient was in bed, the length of time being accounted for by the fact that cutting through the pedicle with the cautery was very tedious. Evening: The patient is weak. Pulse 132; temperature 99°.—19th, 10.30 A.M.: The patient collapsed; pulse hardly perceptible; pain in the abdomen, some distension. Hæmorrhage had evidently occurred; and, with the approval of Drs. Allan and Beatson, ether was administered both by inhalation and subcutaneously, and I opened the wound. I found that the pedicle was bleeding freely, shrinking having taken place and the ligatures ceasing to act. The pedicle was drawn up, and Koerberle's serre-neud, which I had obtained through the kindness of Dr. H. Cameron, was applied firmly round it and left fixed in the lower angle of the wound, the clots were cleared out, and the wound again closed. The form of clamp used was most convenient, as it can be gradually tightened as the pedicle shrinks. Stimulants were freely given and ether injected subcutaneously; but the pulse continued frequent and weak. The patient took stimulants and soup, and subcutaneous injections of ether were continued, as they always appear to improve the pulse.—20th, 11 A.M.: Pulse continues to be very rapid, and at times barely perceptible, patient weak and collapsed looking; it was therefore quite evident that unless some improvement took place soon our patient would die. I accordingly determined to perform transfusion unless there was some improvement by two o'clock. At Dr. Allan's suggestion we gave her warm milk in half teacupfuls every half hour, and this she retained, so that by 2 P.M. her pulse was perceptible and not so rapid. This seemed to be the turning-point, for notwithstanding certain alarming collapses she gradually improved, and was soon able to take any form of simple nourishment. The wound healed once, and the clamp separated on the 28th day, the aperture closing a few days afterwards, and the patient was dismissed well on January 6th, 1883.

Remarks.—The result of the operation fully justifies the procedure adopted; at the same time I feel that but for the splendid nursing she received in the training home, she could not have survived

the double operation. It may be argued that there was no urgent bleeding to call for the tumour being removed, but the discomfort and mental annoyance it caused, along with the acknowledged safety of such operations, were sufficient for agreeing to perform it. Whether removal of the ovaries would have been sufficient I cannot say; but in future cases I shall be inclined to try; especially if the patient is weakened by loss of blood. As regards the tumour, it weighed five pounds, and was a distinct outgrowth, and on section presented a very definite fibroid appearance. Dr. Newman examined the specimen, and found that it presented all the characteristics of a uterine myoma.

Glasgow.

ON COLECTOMY.

By C. A. BALLANCE, M.S. Lond., F.R.C.S. Eng.

THERE are some points in Mr. Lammiman's case of colectomy, published in *THE LANCET* for October, upon which I have a few remarks to offer. I wish also to add brief notes upon the operation of colectomy in general.

1. Mr. Lammiman states that in his case the stricture was scirrhus. I should be glad to hear whether this conclusion was the result of microscopical examination. The hard annular strictures occurring in the upper part of the rectum, sigmoid flexure, or lower end of the descending colon, are usually identical, I believe, with the new growth known as columnar epithelioma. It is not possible to distinguish scirrhus from columnar epithelioma by the naked eye appearance alone. In these cases the new formation is of very slow growth, and before complete obstruction supervenes there is a period during which symptoms referable to the intestinal canal present themselves, and the importance of which at the time they occur is not often recognized. It is interesting to learn that Mr. Lammiman's patient exhibited symptoms of intestinal derangement previous to the occurrence of her fatal illness.

2. I fail to appreciate the advantage of administering, as Mr. Lammiman says that he did, a "competent purgative" when symptoms of acute obstruction are present. Such treatment would appear to me likely not only to increase the present peril of the patient, but would interfere greatly with the chance of recovery if operative measures were subsequently undertaken.

3. There is a point upon which I can throw some light—viz., the passage of the rectal tube for such a long distance, while the stricture was comparatively a small way only from the anus. During the month of February, 1881, I assisted Mr. Pitts at an operation for the relief of intestinal obstruction. The cause of the obstruction was discovered, after making a small median incision of sufficient size to allow the hand to be passed into the abdominal cavity, to be a hard annular stricture of the sigmoid flexure exactly as described by Mr. Lammiman. Previous to the operation I had easily passed the rectal tube for eight inches, and at the operation, simply as an experiment, the instrument was used again, and, on reaching the stricture, was seen to bend upon itself, and to return the way it came.

Mr. Pitts' case was published in the St. Thomas's Hospital Reports, and he was the first, I think, to suggest the operation of colectomy in such cases. Mr. Pitts also pointed out the ease with which colectomy can be performed after gastrotomy, by cutting upon the finger placed within the abdominal cavity, and, further, that in this way a colectomy incision through the abdominal parietes an inch

in length is quite sufficient, and that both the colectomy and gastrotomy wound can be kept completely aseptic until union between the deeper tissues be accomplished.

That colectomy will in the future in a great measure take the place which in the past has been held by colotomy I have no doubt; but I am not so well assured that in this country we shall ever attempt the cure of stricture or gangrene, artificial anus or fæcal fistula, by complete resection of the gut and immediate union of the divided ends with such confidence as continental surgeons. It would appear that the English as a nation are not constitutionally so well fitted to bear operations as the people of some other countries. Last winter I read before the Medical Society of London a case of Vesico-intestinal Fistula following Dysentery, which I had treated by colotomy. I ventured to suggest colectomy for the treatment of like cases when the fistula was not due to malignant disease, and when there was good reason to suppose that the intestine was implicated somewhere below the upper part of the descending colon. By this method the contents of the bowel would escape entirely by the artificial opening, and thus the fistula would have rest from the passage of feces, and might ultimately close. When there is any uncertainty as to the cause of the trouble in patients with obstruction of the bowels, and therefore the possibility that colotomy would fail to afford relief, I think it infinitely preferable to make a small incision in the median line so as to explore the abdominal cavity. With thorough antiseptic precautions the danger of such a proceeding is reduced to a minimum. Not only is there no disadvantage arising from such a proceeding, but, on the contrary, I should look upon it as the pathway of safety. If such a case were to occur to me as that in which Mr. Lammiman performed colectomy in the loin, and the patient would submit to the operation at a period when a satisfactory issue might be anticipated, I should certainly choose the abdominal incision, bring the stricture out through the wound, ligature the bowel on each side of it, excise the stricture with every care to keep the parts aseptic, and then attach the proximal portion of the gut to the margins of a small incision made by cutting down upon the finger placed within the abdominal cavity through the iliac or lumbar regions of the abdominal parietes. Colotomy, again, is often performed on patients suffering from cancer of the rectum to remove obstruction, or for the relief of the pain produced by the passage of feces over an ulcerated surface. It is well known that a portion of the contents of the bowel still passes by the natural channel; it will therefore be obvious that the interruption of the continuity of the gut by ligature or division below the artificial opening would be a great improvement upon the old operation. Colotomy is without doubt a very imperfect method of practice, but it must still find a place in surgical procedure. The hope, however, may be expressed that the day is not far distant when colectomy, or perhaps complete resection of the intestine, will supersede it in many instances.

Harley-street, W.

— *THE Union Médicale* narrates a case of obstruction of the lower third of the small intestines, which proved fatal in a child aged two hours. The cause of the obstruction was found to be due to a mass composed of twenty dead lumbricoid worms and some débris of *gras-double* (fragments of gastric mucous membrane of the ox), of which the child and its parents had partaken abundantly.

SEASIDE DRINKING WATER.

By EDW. NICHOLSON, F.C.S., F.I.C., S.S.C. Camb.,
Brigade Surgeon, Retired List A.M.D.

A NOTE in THE LANCET of a recent date induces me to give some of my experience on its subject. During a varied experience of Southern India I had an opportunity of examining the water-supply of many of its stations, and thus controlling the accounts given of the water-supply of many other stations. A great part of Southern India is "seaside," and much that is now dry land, even plateau-land 1,000 feet high, has been seaside at a comparatively recent geological period. The recognition of this led me to use water analysis as a means of geological investigation as a test of the past history of the country, and the results of prolonged investigation led me to discredit a great part of the sanitary opinions deduced from analyses of water made without sufficient recognition of the past history of the soil. The presence of much chlorides in water is too often concluded to be due to sewage contamination. Waters must not be judged from some abstract standard of purity; in each locality there is a general standard of pure subsoil water, to which the various waters may be referred, and the cause of deviations from the standard must be investigated. More or less salinity may arise, not only from the mineral part of sewage, but from marine salts deposited in various ways:—1. From old deposits in a soil not long risen from the sea. 2. From the residue of saline rain water. 3. From the migration of deposits down the subsoil of a valley to a previously pure spot. Another supposed source is the infiltration of sea water into wells near the shore. But this is far less frequent than is supposed. There may be wells of desalinated sea water, of water purified from salt by filtration; but I doubt whether there are many instances of wells in which originally good water is spoiled by infiltration from the sea. Let us suppose rain falling, for instance, on a coral island; if the rainfall be sufficient, the porous soil will soon become saturated with fresh water which will sink down and displace infiltrated sea water. In course of time the saline deposits will decrease to a minimum, and the island will retain in its porous subsoil a head of water which, so long as it is higher than the sea water, will effectually keep this out. As a matter of fact, all seaside places in which the level of the subsoil water is higher than that of the sea are secure against infiltration of sea water. The greater the rainfall, and the greater the height of the retained water in the subsoil, the more effectual will be the washing out of any marine deposits in the subsoil. Where the land is of comparatively recent upheaval, where the rainfall is small, where the land is too low to keep up a steady outward pressure of subsoil water against the sea, the process of washing out is slow, and the water may be normally brackish. I would instance the whole eastern or Coromandel coast of India. There the rainfall is small, coming principally in bursts which flood the rivers, but do not penetrate the soil thoroughly. Consequently it is found that the water is frequently brackish, except where the well is in the neighborhood of a watercourse. Long after the Indian watercourses, from the small nullah, or ravine of a storm-torrent, to the river half a mile broad, have dried up under the influence of the dry season, there remains an underground sheet of water in the interstices of the subsoil; this sheet of water presses down the valley and supplies any well which may be sunk within its influence. This water is generally free from salinity in proportion to the washing effect it has

had in past times on the subsoil. There is, however, an exception. The moving sheet of water carries along with it a certain quantity of salts, and should it all be drawn to the surface and exhausted by the effect of prolonged drought, its salts are deposited in the soil. Next year's rains dissolve the salts and carry them further down the valley, hence the phenomenon of a diffused mass of salts migrating along the lands and either sterilizing them or rendering the waters brackish during their sojourn. Where the position of the country is unfavorable to this washing-out process the brackishness may be persistent. This must not be confounded, as it is likely to be in seaside places, with infiltration of sea water.

Thus, the salts which cause more or less brackishness in the subsoil water may not be from original marine deposits in the soil; they may be deposits by rivers or torrents which have since taken another course or which have dried up. And it must be remembered that salts may not be marine in the ordinary sense. There is a perpetual circulation of salts between sea and land, and, though it is probable that the sea is becoming, in the present geological period at least, more and more saline, yet a great part of the millions of tons of salts swept every hour, nay every minute, into the sea is being continually restored to the land. A remarkable instance has recently come under my notice. I began some weeks ago an examination of the waters of Guernsey, where I was then stationed, and I was surprised to find that the purest subsoil water contained nearly eight parts in 100,000 of sodium chloride, out of a total of seventeen parts of mineral constituents left on evaporation. This water was from a well in which the water lies at about 230 ft. above the sea-level and 60 ft. from the surface; the well is about a quarter of a mile from the edge of the cliffs; its situation and surroundings (in an unmanured field, without any buildings within several hundred yards, and pumped by machinery) are such as to remove all suspicion of contamination. Yet, what would theory not say of a water containing 4·6 centigrammes per litre of chlorine and 1·1 centigramme of nitric acid? Its quality would be expressed in terms of London sewage. Other waters from wells of equal purity were found to contain 5·3 centigrammes of chlorine and 1·9 of nitric acid in the litre. The approximate constitution of the solids was as follows:—

	Centigrammes.
Alkaline chloride.....	8·7
Alkaline sulphate.....	4·0
Nitrates.....	2·3
Earthy silicates.....	4·5
Earthy carbonates.....	3·3

22·8 per litre.

The hardness of the water was 9·6° (centesimal scale).

	Centigrammes per litre.
Ammonia, free.....	·002
Ammonia, albuminoid.....	·0056
Oxygen required by the permanganate process.....	·003

Whence could come these large proportions of marine salts, more than half of the solid constituents of the waters? The subsoil of Guernsey is gneifs, and the wells are cut in this rock. The source of the salts is to be found in the high salinity of the air saturated with marine vapors, and I have no doubt that the whole of the salts are air borne. These salts are continually being returned to the sea by the streams which pour down every valley and trickle from every cliff, but they are restored to the island as fast as they are washed away.

I regret that my departure from Guernsey cut short these investigations of an interesting subject. I, however, ascertained another fact bearing on the present subject. Several wells supplying houses on the esplanade in the lower part of St. Peter's Port (for the whole island is dependent on wells and rain-water cisterns) were found to yield brackish water. In some cases there was obvious sewage contamination, but where this was not evidenced by the amount of ammonia, it was pleaded that marine infiltration might be the cause of the salinity. I found, however, that several of the wells on the slope of open ground above this esplanade were equally, or nearly equally, saline and nitrous, and the circumstances pointed to a large cemetery and several streets of houses on a higher level as the sources of the salinity. As the drainage of the town is of comparatively recent date, it may be imagined that the subsoil of the thickly inhabited parts is considerably contaminated by sewage. The wells in contaminated ground usually yielded about 20 centigrammes of chlorides, 5 to 12 of sulphates, 8 to 14 of nitrates, out of a total of about 60 centigrammes of mineral solids per litre. The hardness ranged from 22 to 31 degrees centesimal ($1^\circ = 1$ centigramme per litre of calcium carbonate).

Returning to my Indian experience, I may mention that on the low Coromandel coast, where there is a comparatively scanty rainfall, wells near the seashore are frequently found to contain brackish water, while elsewhere conditions more favorable to washing out of salinity from the soil are accompanied by freedom from salinity, even though the wells be in very porous soil, and very near to the seashore. Thus on the western, or Malabar coast, the heavy rainfall has long ago washed all salinity out of the porous soil; wells near the shore, and dug down to the sea level (as evidenced by the sand at the bottom and the general level) yield water remarkably free from any salinity except that due to air-borne chlorides. The reason is, as I have said, that in every place where the rainfall is sufficient to wash the soil free of any original marine deposits, it will exercise a pressure sufficient to prevent all infiltration of sea water. Therefore, whenever the level of the subsoil water is above that of the sea, any salinity not due to sewage contamination must be ascribed to marine deposits or air-borne marine salts. Infiltration of sea water could only occur where the subsoil water was lowered by continuous drought. Could it, however, be produced by the pressure of high tides? I cannot answer the question positively, but I would venture to say that the fluctuating level of the sea could scarcely have effect at any considerable distance from high-water mark, and that high tides would only press back the water which low tides had drawn to the shore. The physical effect of the sea on the subsoil water of seaside places is then the same as that of other sheets of water, lakes, ponds, or rivers. Everywhere the level of the subsoil water is not below that of the sheet of water towards which it tends to flow. Apparent exceptions to this rule may occur where irregular cropping up of impervious strata dams the slope; but the rule here holds good as regards the underground sheet of water thus dammed up, though it may be a small supply, and soon exhausted. Where the sheet of water is the sea, the subsoil water can always be reached at a depth less than that of sea level, and less in proportion to the distance from the shore. And unless the subsoil water be exhausted by continuous heavy drought, in a well not far from the sea and sunk in very porous soil affected by tides, I do not think that infiltration of sea water can occur.

Palace-gardens-terrace, W.

A Mirror OF HOSPITAL PRACTICE, BRITISH AND FOREIGN.

Nulla autem est alia pro certo noscendia, nisi quamplurimas
et morborum et dissectionum historias, tum aliorum tum proprias
collectas habere, et inter se comparare.—MORGAGNI *De Sed. et
Caus. Morb.*, lib. iv. Proœmium.

MIDDLESEX HOSPITAL.

CASES OF STRANGULATED HERNIA.

(Under the care of Mr. HULKE.)

THE many variations in their anatomical and pathological circumstances which herniæ offer have ever given to them a peculiar interest. The first of the following cases illustrates a not infrequent complication of the ordinary form of congenital scrotal rupture—a constriction of the sac at some distance below the external abdominal ring separating an upper from a lower compartment, the tunica vaginalis enclosing the testis. Such constriction, more than one may be present, marks a spot where there has been an approach to obliteration of the tube of the funicular process. Its significance in relation to strangulation is evidenced by the greater intensity of the congestion, etc., usually found in those parts of the protruded viscera occupying the sac below it, and also by the resistance it offers to their extrication and replacement in the belly after their complete liberation from constriction at the abdominal rings, an impediment which deceptively simulates that caused by adhesions of the viscera to the bottom of the sac or testis. Perhaps such complications account in some measure for the greater mortality of strangulated congenital ruptures noticed by more than one writer of eminence. The anatomical circumstances in the second case nearly resembled those in the first. The third case illustrates a very frequent event: the supervention of hernia upon retention of the testis in the inguinal canal. In the fourth case the inconveniences incidental to this *error loci*, together with the evidently imperfectly developed condition of the organ, justified its removal, a measure the propriety of which would have been doubtful had the organ been sufficiently mobile to have allowed its being drawn down out of the inguinal canal and planted in the scrotum, or even replaced in the belly. The fourth case exemplifies one of the gravest accidents that can happen in connection with a strangulated hernia—its reduction *en bloc* or *en masse*, by an improper use of the taxis, not infrequently by the efforts of an unskilful patient, who in his anxiety and suffering makes violent and ill-directed pressure in his attempts to reduce the hernia. After such an accident the surgeon who then first sees the patient, and is not informed of the previous circumstances, may, in the absence of an external hernial swelling, pardonably ascribe the symptoms to an internal intestinal obstruction. But reduction *en bloc* may also occur in herniotomy where the sac is not opened, and a thin shell of fascia or condensed subserous tissue external to the sac has been mistaken for this latter, in which case after liberation of every constriction at the abdominal openings, the sac still enclosing the protruded viscera may by injudicious pressure (which need not, however, necessarily be great) be detached from its surrounding connections, and slip up within the belly. This accident (which, oddly enough, was thought by an eminent author to oc-

cur only in inguinal hernia) appears to be more frequent in the femoral variety. Three instances of this occurred within the writer's knowledge in the course of one year in the practice of three surgeons, two of whom had a large experience in herniotomy, and the third one had already operated in several cases. In two of these cases persistence of symptoms caused a suspicion of the accident. The wound was opened up, the unopened sac, with its neck girdling tightly the intestine within it, was found outside the peritoneal cavity, below the pelvic brim brought into view and opened; the stricture formed by the neck of the sac was divided, and the gut replaced in the belly, but too late to avert a fatal issue. Of three cases within the writer's knowledge of reduction *en bloc* of inguinal hernia by improper taxis, two of the patients were males; in the other case, the rupture had habitually distended the left labium pudendi. The persistence of symptoms of obstruction, after an apparently successful reduction of the rupture, led to an exploration of the inguinal canal. The sac was found above the position of the internal abdominal ring, in a subserous space between the peritoneum and fascia transversalis. It was brought down, opened, and the intestine was liberated and reduced, but in this case also the error was recognized too late to save the patient's life. The interest of the fifth case lies in the early time of the operation—one hour after the occurrence of strangulation. Here, in view of the urgency of the symptoms, any delay would have been dangerous.

CASE 1. Strangulated Congenital Scrotal Rupture; Hour-glass Contraction of the Sac; Herniotomy; Recovery.—On June 12th, 1882, a cabinet-maker, aged twenty-five, who had previously occasionally noticed a fullness in his left groin, fell whilst running. He instantly felt severe pain in that region, and had great nausea. He found his scrotum swollen, and soon began to vomit. Two hours after the accident he was admitted into the hospital. The right inguinal canal and corresponding side of the scrotum were distended by a rupture, the scrotal portion of which, by its tenseness and the absence of impulse, was unmistakably strangulated, but this could not be certainly ascertained with respect to the inguinal portion. His suffering was very great; he writhed with pain; and he retched frequently. Anæsthesia was induced with ether, and, the taxis failing, herniotomy was at once performed. Reduction proved impracticable until the sac had been opened, when the obstacle was found to be a diaphragm-like septum, which subdivided the scrotal portion into an upper and a lower compartment, the latter of which also contained the testis. Division of the edge of the small opening in this septum liberated a knuckle of very congested small intestine, after which reduction was easily effected. On the 30th of the same month the man left the hospital convalescent.

CASE 2. Strangulated Bubonocoele; Serous Distension of the Scrotal Parts of the Funicular Process; Herniotomy; Hæmorrhage on the following day necessitating opening up of the Wound; Recovery.—A man, aged twenty-three, received through his horse falling a severe blow in the right groin, causing intense pain there. After a few minutes this abated so that he was able to remount and ride home, but three hours later it returned with increased intensity and he then began to vomit. On the following morning he was first seen by a doctor, who recognized the presence of a rupture and tried the taxis and ice, and as these measures failed he sent the man into hospital. Upon admission, about twenty-four hours after the injury, his right inguinal canal was found occupied by a very

tense, painful, and tender swelling, from which a painless, less tense, fluctuating oblong process, extended through the external abdominal ring into the scrotum. As the symptoms were acute and the strangulation had already lasted twenty-four hours, the rupture was immediately submitted to operation. The inguinal parts enclosed a knuckle of small intestine intensely congested. The scrotal part contained only serum. It communicated with the inguinal at the external ring by a circular opening of the size of a No. 10 catheter. The strangulation was at the internal abdominal ring external to the sac. In the following afternoon hæmorrhage occurred so free that the house-surgeon felt compelled to open the wound. The bleeding proceeded from several small arteries in the scrotal incision; they were secured. The bowels acted first on the thirteenth day, and on the twenty-third day the man was dismissed convalescent. The occurrence of such hæmorrhage is very exceptional.

CASE 3. Retained Testis; Strangulated Bubonocoele; Herniotomy; Removal of Testis; Peritonitis; Recovery. (From notes by the dresser, Mr. Stace).—An engineer, aged twenty-one, whose right testis had not descended into the scrotum, whilst straining in the watercloset suddenly felt pain in his right groin, and placing his hand there found a swelling. Within a few minutes of this occurrence he vomited, and he was sick again later in the day. Suffering acutely he took two opening pills, and as those did not act and his distress grew greater he was brought next day to the hospital. His right inguinal canal was occupied by an excessively tender, painful swelling, the lower end of which protruded slightly through the external abdominal rings. The intensity of the pain in the belly would not let him lie still, but he tossed about restlessly in bed. His face was pale and his pulse quick, small, and weak. There could not be any doubt that the swelling was an acutely strangulated bubonocoele. Ether was given, the taxis gently tried for a couple of minutes, and failing, herniotomy was immediately done. The sac contained about an ounce and a half of turbid bloody serum and a knuckle of distended, purplish-brown small intestine. The constriction was in the neck of the sac. Behind the gut was the testis, not larger than a small nut, and flabby. As it was evidently imperfectly developed and presumably functionally useless, and its situation exposed it to violence and would have made difficult the wearing a truss, it was removed. A sharp attack of peritonitis followed the operation. It was treated with opium internally, by mercurial inunction on the thighs, and the application of leeches, followed by fomentations to the belly. Coincidentally with the appearance of slight soreness of the gums the abdominal symptoms began to abate; they rapidly disappeared, so that by April 6th he had recovered as regarded the hernia, and was about to be dismissed when an attack of pleurisy necessitated his transfer to a medical ward.

CASE 4. Strangulated Inguinal Rupture; Reduction en masse; Herniotomy; Recovery. (From notes taken by the dresser, Mr. G. Cree).—An engineer, aged fifty-nine, who had been ruptured in both groins for twenty years, and had worn an inefficient truss, which sometimes let the ruptures slip by it into the scrotum, was seized with vomiting after eating heartily of pork on the evening of Jan. 1st. For this a druggist gave him purgatives. As these did not act, and his disorder increased on the 4th, he was seen by a medical man, who, learning he was ruptured, examined his groins, and not finding any swelling there, regarded his symptoms as indicative of an internal obstruction, and prescribed belladonna and opium. On the following

day he first detected a swelling in the right groin, and sent him into the hospital. The swelling was clearly a strangulated bubonocoele. The patient's cheeks were pale and sunken; the surface of the body generally was cold. The pulse was small, weak, and rapid. He vomited frequently, and the matter thrown up had a faecal appearance and smell. At this stage it was judged improper to repeat the taxis, which had already been tried by the former medical man, and herniotomy was done without delay. The sac was found to be very thick, and much congested. On opening it two ounces of bloody serum escaped, and the opening being enlarged several coils of small intestine protruded, the quantity being much greater than could have been contained in the inguinal canal. Most of this intestine had occupied a deeper part of the sac lying deeply in the belly between the fascia transversalis and the peritoneum. By drawing this down, the neck of the sac, which constituted the constriction, was brought within reach and divided, after which the gut, very congested and thickened, but not gangrenous, was easily replaced in the peritoneal cavity. The wound was washed out with chloride of zinc solution (forty grains to one ounce of water), and a drainage-tube inserted. A slip of oiled silk, covered by a pad of borie lint, secured by a bandage, completed the dressing. He passed a copious loose stool the same evening. His recovery was uninterrupted, and on the 16th of the month, eleven days after the operation, he was able to return home. The anatomical circumstances disclosed at the operation leave no doubt that by an improper application of the taxis by the patient himself the upper part of the sac had been detached from its connections in the inguinal canal, and thrust up more deeply in the belly, becoming bulged and punctured, but not torn. The straining attending the continued retching forced it again into the canal, and led to its detention here.

CASE 5. Large Strangulated Scrotal Rupture; Operation one hour after the accident; Sac Unopened; Quick Recovery. (From notes by the dresser, Mr. G. Cree.)—An enameller, aged forty, whilst at his furnace felt sick, as he thought, from the metallic fumes rising from his work, and beginning to vomit found his scrotum swell, and he was seized with severe pain in it and in the belly. When admitted into the hospital soon afterwards he was found to have an extremely tense scrotal rupture, of the size of a cocoanut. He was writhing with pain. His face and hands were cold, and bedewed with sweat. He had, he said, been ruptured for several years, and had worn a truss. As the rupture was irreducible by taxis, and its great tenseness and the severity of the symptoms indicated a very tight strangulation, it was subjected to operation one hour after the onset of the symptoms. After division of the margin of the external abdominal ring, and of some tight fibrous bands external to the neck of the sac, the contents were reduced without opening this latter. The bowels acted the same night. The wound healed by first intention.

KIDDERMINSTER INFIRMARY.

TWO CASES OF STRANGULATED HERNIA.

(Under the care of Mr. J. LIONEL STRETTON, honorary surgeon.)

CASE 1.—E. G—, aged thirty-three, female, unmarried, has been ruptured for two or three years and worn a truss, but latterly has left it off because it was uncomfortable. While straining at her work, carpet weaving, it came down, and she has not been able to return it. She was first seen

on May 31st, the following day. She was lying in bed, her expression anxious; her bowels had not been open since the 29th. She had vomited several times on the 30th; the vomit was said to be of a yellow color. There has been no sickness to-day. On examination there was found a small nodular swelling just below Poupart's ligament (right side) in the region of the saphenous opening. It is slightly red, very painful to the touch, resonant on percussion, no impulse on coughing. A slight attempt at taxis was made, and this failing she was ordered into the infirmary. On admission she was placed in a warm bath, and a further attempt at taxis made, but without success. After consultation she was placed under chloroform; another attempt at taxis was made, and this failing it was decided to operate. A vertical incision was made over the tumour and the sac carefully exposed; but as no constriction could be felt the sac was opened. The constriction was found at the femoral ring, which was very high up. The internal edge was nicked with a herniotome, and the gut easily returned. There was no omentum in the sac, and the gut was quite healthy though very tightly constricted. The wound was closed with silver sutures, a small piece of drainage-tube inserted at the lower end, and dressed with carbolic oil lint. To have one grain of opium pill at once, and half a grain every three hours. Iced-water to sip.

June 1st: Has had very little sleep. There has been no sickness. Slight pain in the region of the wound, but no oozing from the dressings. Tongue moist. Temperature 99.8°; pulse 116. To have one grain of opium every four hours. To have milk.—2nd: Has had a better night and feels more comfortable; passed flatus several times during the night; tongue moist. Temperature 101.4°; pulse 116. To have opium every six hours.—4th: Patient doing well; is menstruating; wound dressed, nearly healed; one stitch removed; opium stopped. Temperature 100°; tongue cleaning. To have beef-tea.—5th: Wound dressed again, remaining sutures and drainage-tube removed. Complaints of discomfort; the abdomen somewhat distended. To have enema of milk and assafetida.—7th: There has been no action of the bowels, still a good deal of distension. To have enema of gruel, castor oil and assafetida. Wound healed except aperture of drainage-tube.—8th: Bowels open twice in the night; she is much more comfortable; tongue clean. To have fish.—12th: Patient practically well. To have mutton chops.—20th: Truss ordered, but owing to a sore just below the left anterior superior spine she was unable to wear it and had to remain in bed a week or so longer, at the end of which time she was discharged cured.

CASE 2.—J. G—, male, aged seventy, married; first seen on July 11th at 8.45 p.m. He was in bed complaining of great pain and sickness, and said, "I think I am ruptured." Upon inquiry he said that he was mowing with a scythe at 1 p.m. when he felt something give way, and he was seized with great pain in his right groin. He was vomiting continually, the vomited matter was curdy, not faecal; his bowels had not been open for three or four days; since the accident he had wanted to stool but could not. Examination revealed a small swelling about the size of a walnut in the right groin, a little internal to the centre; it was so tender that no minute examination was made, but he was advised to go into the infirmary. At 10 p.m. he was seen at the infirmary, and after a consultation was placed under chloroform, and an attempt at reduction by taxis was made; this failing, the operation was proceeded with. The usual incision was made and the sac carefully exposed. It was then found necessary to open the sac, which

was accordingly done, when it was found to contain a small knuckle of healthy intestine and a larger piece of omentum, also healthy; the constriction, which was at the internal ring, was very light. Two little nicks were made in it, and the bowel and omentum easily returned. The wound was brought together with silver sutures, and dressed with carbolic oil lint. To have ice and water, a grain of opium in pill at once, and half a grain every four hours.—12th: Had a comfortable night, slept several hours. Much less pain; no sickness since operation. Temperature 100.4°; pulse 78; tongue dry. To have iced milk.—13th: Passed flatus several times yesterday and in the night; partakes freely of iced milk. Temperature 100°; pulse 70; tongue not so dry. To have a quarter of a grain of opium every four hours.—15th: Going on well. Tongue moist; temperature 99.6°; pulse 60. Dressed; nearly healed except lower part; upper sutures removed. Bowels acted this afternoon; motion natural. To have beef-tea; opium to be stopped.—20th: Is going on very well; temperature normal. Wound not quite healed at lower part. Bowels not open since the 16th. To have enema of castor oil and gruel. After enema bowels acted several times. To have mutton chop.—26th: Quite well. Tongue clean; bowels open; appetite good. Wound not quite healed.

Aug. 1st: Wound healed. Truss ordered.—8th: Discharged cured.

Remarks.—These two cases are instances of rapid recovery after operation for strangulated hernia without the so-called antiseptic (Lister) treatment. The success I attribute to two reasons:—(a) The early operation. (b) The absence of any rough manipulation. In neither case was there the slightest room for anxiety after the operation. In the first case the temperature never exceeded 101.8°, though we had the extra upset of menstruation on the fifth day; and in the second, a patient of advanced age, the temperature never exceeded 100.8°. That the operation *per se*, if all due precautions as to cleanliness be taken, is not one of extreme danger, I feel sure. And if cases were only seen early enough, and the operation at once resorted to before too vigorous attempts at taxis had been made, the mortality would, I think, be greatly reduced.

GENERAL HOSPITAL, BIRMINGHAM.

TWO CASES OF MALIGNANT DISEASE OF THE OESOPHAGUS; GASTROSTOMY IN ONE CASE, INCOMPLETE GASTROSTOMY IN THE OTHER; DEATH; NECROPSY; REMARKS.

For the following notes and remarks we are indebted to Mr. Gilbert Barling, M.B., F.R.C.S., resident surgical officer.

Malignant Disease of the Oesophagus; Gastrostomy; Death; Necropsy. (Under the care of Mr. Bartleet).—Richard W—, aged forty-five, was admitted on May 9th, 1883, complaining of difficulty in swallowing his food. He stated that in the previous September he was almost choked in swallowing some meat, since which time he had had to wash his solid food down by drinking very frequently. For six weeks before admission he had not taken anything solid, and occasionally had swallowed fluids with difficulty, especially early in the morning. He had not vomited either blood or pus.

On examination it was found that the man could take milk in small quantities with but little discomfort, but that on attempting to swallow bread or minced meat he experienced much pain, referred to the top of the sternum; this was followed by

eructations until the solid particles were vomited. A bougie passed twelve inches from the teeth before encountering any obstruction. There was no history of traumatism, nor evidence of syphilis or malignant disease to be found in the glands, etc. Loss of flesh was said to be considerable; the urine was of rather low specific gravity, contained a trace of albumen, and an occasional cast.

After consultation with his colleagues, Mr. Bartleet determined to perform gastrostomy, the patient expressing his willingness to undergo any operation, as he was so troubled with hunger. The first part of the operation was performed on May 18th (the method of Howse, as described by Mr. Durham in Holmes's "System of Surgery," being adopted). The abdomen having been opened in the linea semilunaris, a double ring of sutures was inserted to bring the stomach and parietal peritoneum in broad contact. Finding a handled needle inconvenient for passing the outer ring of sutures, Mr. Bartleet adopted the following plan: a piece of silk was threaded with a needle at each end; one needle was passed through the outer coats of the stomach, and then each needle thrust vertically through the abdominal wall an inch from the edge of the wound; six of these sutures were placed in position, and then each was tied over a piece of catheter. The wires first used to fix the stomach were left *in situ*. Lister's method of dressing was employed.

There was no vomiting after the operation. Nutrient enemata were administered every four hours and the lips moistened with water, no food being allowed by the mouth until the second day, when two teaspoonfuls of milk were given by the mouth every hour, and this quantity was gradually increased until May 29th (eleven days after the first operation), when the stomach was opened with a tenotome. Through the opening milk was cautiously introduced, and eventually eggs, broth, and minced meat, the enemata being stopped altogether on June 7th. For a time the patient gained ground, and was so well as to be able to take a little walking exercise, but at the end of June he suffered much discomfort from a profuse flow of gastric juice from the fistula, which could not be controlled, as he could not bear the pressure either of a flat pad or of a plug in the orifice, owing to the pain these caused in the abdomen. He now became much weaker and thinner, and about the middle of July took to his bed again, and died in the tenth week after operation.

The necropsy made by Mr. Puyne revealed a stricture in the oesophagus two inches and a half from the stomach; it was nearly an inch in length, and admitted a body about the size of a No. 10 catheter. There was no ulceration, nor was there dilatation above the stricture. Microscopically it proved to be a carcinoma, which would be best defined as an atrophying scirrhus; there were no secondary deposits. A large gland at the bifurcation of the trachea was suspected of carcinomatous enlargement; but on microscopic examination no evidence was found of epithelial infection. The stomach was attached to the abdominal wall by very firm adhesions, which extended from the fistula for fully an inch in every direction. On opening the viscus, its mucous membrane appeared healthy and its cavity uncontracted, the fistula was found to open about an inch nearer to the pyloric than to the cardiac end, and about midway between the upper and lower borders. An abscess cavity capable of holding nearly a pint of pus was found adjacent to the upper border of the stomach; lying first of all between that viscus and the liver, then passing over the edge of the liver, it was limited below by that organ and the spleen, and above by the diaphragm. The left

lung was firmly adherent by its base to the diaphragm. The kidneys were cirrhotic.

Malignant Disease of the Oesophagus; Uncompleted Gastrostomy. (Under the care of Mr. Jolly.)—J. L—, aged fifty-eight, was admitted on April 26th, 1883, complaining of inability to swallow his food. The patient first came under observation in October last, with enlarged glands below the pinna of the left ear, these were hard, irregular, and fixed; but there was then no complaint of dysphagia, and although it was suspected that the glands were enlarged secondarily to a malignant growth elsewhere, nothing could be discovered in such parts as were accessible to examination. About May the patient noticed that he had pain in swallowing his food, the pain being referred to the middle of the sternum. This trouble increased steadily, so that at the time of admission he dreaded taking any solid food, which at times stuck in the oesophagus and was vomited, but the vomit did not contain either blood or pus. There was evident rapid emaciation. The glands at the side of the neck were much larger than they were in October, and they displaced the trachea to the opposite side; the left axillary glands were also enlarged. Nothing abnormal was to be seen or felt in the air or food passages. Bougies were not passed.

Gastrostomy was decided upon, and the first stage of the operation was performed on May 15th, the abdomen being opened in the linea semilunaris and the stomach stitched to the abdominal wall by one ring of sutures, which transfixed only the outer coats of the stomach, and were then passed through the edge of the wound. Listerism was followed in the dressings. Nutrient was administered by the rectum for the first thirty-six hours only, after that a little milk was allowed by the mouth. There was no vomiting after the operation and hardly any complaint of pain, but thirst was very troublesome. The patient progressed fairly for three days, at end of which time it was evident that he was losing strength, and that his blood aeration was not well performed. He died on the morning of the 20th, the stomach not having been opened.

The necropsy made by Dr. Windle showed a stricture in the oesophagus midway between the cardiac end of the stomach and the crossing of the aorta. The strictured portion felt very hard, and there was no ulceration. Microscopic examination demonstrated that the stricture was carcinomatous; in parts the spheroidal cells, and in others the stroma, predominating. The stomach had been secured at one-fourth from the cardiac end, and at one-third upwards from the great curvature. There was a circle of adhesions between the viscous and the abdominal wall, with a diameter of about an inch; these were moderately firm, but some gave way on handling. The only secondary deposits found were those above-mentioned in the neck and axilla. The right lung was pneumonic almost throughout, in the state of grey hepatization.

Remarks.—There are some points in these cases to which attention should be called. With regard to the outer ring of sutures, the plan followed in the first case is more convenient than that advised by Mr. Durham, and not only more convenient, but safer, as harm is less likely to happen to the stomach walls. It is very important when opening the stomach to make a mere puncture only, as the wound so readily gapes; and this puncture should be made between the wire holders, which it is important to retain, with a quick vertical thrust, for the stomach wall is so thickened and yielding that it would be very easy to separate the adhesions, and so open the peritoneal cavity, as

was demonstrated in the second case when the body was on the post-mortem table. Although the abdomen was open in each case through the linea semilunaris, there was considerable difference as to the position at which the stomach was secured, an important detail, because it has probably been a bar to greater success in many cases that the stomach has been opened too near the pylorus or to the lower border. A suggestion made by Mr. Butlin may obviate this difficulty. It is that a vertical incision be made in the abdominal wall and the stomach carefully examined before it is stitched in the wound, so that a suitable part may be opened; the vertical incision enlarged either way would give more room for this purpose than the curved. The existence of the abscess in the completed case was a great surprise, as there had been nothing to suggest its existence during life; but it is probable that the pain which came on when pressure was applied to the orifice of the fistula was due to the compression of the abscess sac, and so this complication must be regarded as interfering with the more complete success of the operation. How the abscess arose is not easy to explain, but it is most likely to have commenced at the irritation around one of the outer sutures; two of these were left *in situ* until the seventh day, when there was a little suppuration around them, and from this the abscess possibly extended. But the most important consideration is whether the patients gained by the operation. As regards relief from hunger, the first patient was much benefited; whether his life was prolonged it is difficult to say. It must be conceded that the second patient's life was rather shortened than lengthened, as the pneumonia which caused his death was probably due to the operation and the subsequent rigid confinement to the recumbent position. It teaches one lesson, however, that where operation is meditated it should not be deferred until the patient's powers are too far diminished to bear the strain that will be thrown upon them; in fact that gastrostomy should not be looked upon as a forlorn hope, but that it should rather be regarded as a palliative in the light that colotomy is. The pathology of the growths is interesting; the first was an undoubted scirrhus carcinoma; the second, too cellular to be defined as scirrhus, was yet not an ordinary epithelioma, neither from the type of its cells nor their arrangement. The glandular affection, too, arising in the second case before complaint of oesophageal obstruction is worth alluding to.

ASHBURTON AND BUCKFASTLEIGH COTTAGE HOSPITAL.

SEVERE HEAD INJURY, WITH TOTAL UNCONSCIOUSNESS FOR ELEVEN DAYS AND PARTIAL FOR FORTY-THREE DAYS; FRACTURE OF LEFT LEG; RECOVERY.

(Under the care of Dr. JAMES ADAMS.)

F. A—, a butcher's boy, aged twelve, was admitted on the evening of September 7th, 1882. He had been thrown from his horse and dragged a considerable distance with his left leg caught in the stirrup. He had sustained the following injuries:—Two lacerated scalp wounds over the left parietal region and a deep wound along the left eyebrow, all extending to the bone; division of the left upper eyelid; both eyes closed by the swelling all about them; nose and left cheek excoriated; both lips swollen; fracture of the left leg just above the ankle, the inner point of the upper fragment of the tibia projecting prominently beneath the skin, this point being subsequently pushed

through, converting it into a compound fracture. About half way up the leg on the inner side venous blood was freely flowing from a small wound, into which a probe could be freely passed for some distance in a downward direction. Neither at first nor afterwards could any fracture of the skull be detected, although the symptoms and course of the case indicated serious brain lesion.

When admitted into the hospital the boy was unconscious and almost pulseless. The skin was pale and cold. With difficulty the boy was made to swallow a little brandy and water. He passed urine in the bed involuntarily in the night. The wounds were dressed with carbolized oil. The leg was put up with a back and two side-splints. The ward was kept darkened. The head was shaved, and cold water applications kept up as far as possible. Milk diet and brandy were given, and three grains of calomel were administered at night for three nights.

Sept. 8th, 10 A.M.—Temperature 98°; pulse 150, soft and variable. Breathing shallow and irregular. Restless night. No urine voided during the day, and in the evening a catheter was passed and the bladder emptied. This was done twice a day for a fortnight. An enema with castor-oil in it was given daily.—10th, 11 A.M.: Temperature 99°. Bad night, very restless, turning from side to side and displacing the leg splints. Scalp wounds doing well. Takes milk freely.—12th, 8.30 P.M.: Temperature 100.4° (this was his highest temperature). Restlessness continues by night and day; he is scarcely still for a minute. Had to put up the fracture again under a whiff of chloroform, the projecting point of the fractured tibia causing redness of the skin and threatening to come through. Gave him ten minims of Battley's solution each night.—17th, 10.10 A.M.: Temperature 97°. Breathing shallow and very irregular. Pulse soft and very variable. Still restless and tossing about, and requiring constant supervision to prevent his falling out of bed. First spoke this evening, asking for drink. Ten drops of Battley's solution were given at night, and five in the morning.—23rd: Extreme restlessness continues. The tibia thrust through the skin by the constant twisting and moving of the leg, making the fracture compound. The splints had to be again adjusted under chloroform. Noisy, shouting frequently for nurse, drink, etc. Takes milk and broth well, and sometimes an egg. The bowels act involuntarily and urine passed in bed involuntarily. Instead of opium, chloral hydrate and bromide of potassium were given.

October 7th.—Very restless and noisy, requiring very close attention to prevent his falling out of bed. Mind a little clearer. Kept repeating a word or sentence. Began to know when his bowels acted; also knew when he wanted to pass water.—10th: More irritable and restless. Impossible to keep the splints in place. A wound as large as a florin above the inner ankle caused by the movements of the fractured tibia. Not the slightest union between the fragments. Appetite good. Chloral hydrate and sedative solution of opium were given every four hours. The opium was gradually increased till in one day, in the course of twenty-four hours, he took a drachm of Battley's solution and a drachm and a half of chloral hydrate without any ill effect. This combination seemed to quiet him more than anything else he had taken.—18th: Mind distinctly improved and restlessness less. Had a fit of weeping, and was grieving bitterly about his friends and saying they were angels. The draught only required at night.—21st: Mind clear and right. No restlessness. Keeps the leg still. Put up fracture for the last time in fairly good position.

November 28th.—Fracture has united; starch bandage applied. The boy was allowed to get out of bed for the first time.

December 19th.—Discharged with brain power natural. Firm union of fracture with only three-quarters of an inch shortening. A small bit of bone from the projecting end of tibia necrosed and came away, and the wound after this healed kindly.

Remarks.—There were two points of special interest in this case—viz., the prolonged and acute cerebral symptoms followed by complete recovery, and the good result of the compound fracture notwithstanding its having undergone for six weeks such constant and severe disturbance before it was finally set.

SEAMEN'S HOSPITAL, GREENWICH.

TROPICAL ABSCESS OF LIVER; FREE INCISION; ABSENCE OF PERITONEAL ADHESION; RECOVERY; REMARKS.

(Under the care of Dr. CARRINGTON and Mr. JOHN-SMITH.)

For the following notes we are indebted to Mr. W. T. Hodge, clinical assistant.

H. H—, boatswain, aged thirty-two, was admitted on Aug. 9th, 1883. The patient had been frequently in tropical climates. He contracted dysentery three years previously in Calcutta, but got quite well of this. Two months before admission he had an attack of severe pain in the "pit of the stomach." This was continuous and aching in character, and went off after twenty-four hours. The present illness commenced on Aug. 4th, 1883, when the patient was seized with severe pain in the epigastrium, which was followed shortly afterwards by pains between the shoulders and in the lumbar region. He had suffered in this way up to his admission. He had no rigors, but constant sweating, great thirst, and loss of appetite. The bowels acted about six times in the twenty-four hours, the evacuations being rather light in color.

Condition on admission:—The patient lay upon his back, with anxious expression and somewhat restless. The skin was hot and dry; the tongue was thickly coated with yellow fur. There was dulness on percussion in the right hypochondriac and epigastric regions, extending as far as two inches below the free margin of the ribs, and reaching across the median line as far as the eighth costal cartilage. The upper limit could not be defined on account of the excessive tenderness. Pressure over this area caused great pain, more especially at a point three inches above the umbilicus, a little to the right of the middle line. Neither pain nor gurgling was elicited by pressure on the right iliac fossa. Respiration 30, thoracic, shallow, with a catch at the end of inspiration; breath-sounds normal in front and axillary regions; heart normal; pulse 98; urine albuminous; temperature 104.8°.

On August 10th there was perceptible bulging at the part that was so markedly tender on the previous day. Poultices were applied over the right hypochondriac region, with the result of much diminishing the pain and tenderness, so that the swelling could on Aug. 11th be freely touched and handled, whilst formerly the slightest touch made him wince. On the 12th an exploratory puncture was made at a point two and a half inches from the median line, and half an inch below the margin of the ribs, the needle being passed upwards and backwards. When three inches had been inserted pus was discovered; it was perfectly sweet.—Aug. 10th: Morning tem-

perature, 101.8°; evening 101°.—11th: Morning temperature, 99°; evening 100.4°.—13th: Morning temperature, 98.4°, before the operation; evening, 101.8°. On the 13th the patient was placed under the influence of ether, and Mr. Johnson-Smith introduced an exploring needle just below the right ribs, and again drew off pus; under the carbolic spray he then made a vertical incision two inches long, passing through this spot. A director was passed into the abscess, and a free incision made into the cavity by a blunt-pointed bistoury passed along it. About a pint of pus and broken-down liver substance, mixed with blood, escaped. The finger introduced through the incision passed through about an inch of liver into a large abscess sac, and it could also be freely passed into the peritoneal cavity, for no adhesions existed. A large drainage-tube was introduced. The abdominal wall was pressed down upon the liver by two large sponges bandaged on, and the wound was dressed with antiseptic precautions. On the 14th the patient felt quite comfortable. The wound was dressed, and there was a large quantity of discharge upon the dressings. This was perfectly sweet. There was no oozing of pus from the wound. The cavity was not washed out, for fear of destroying newly formed adhesions. Morning temperature, 98.4°; evening, 98.2°.—15th: He slept well last night, and this morning was in no pain. The wound was dressed to-day, and the abscess cavity syringed out. It was looking very healthy. Morning temperature, 98°; evening, 99°.—16th: Patient has been going on well. His appetite has returned. Fish diet ordered. Morning temperature, 98.2°; evening 98.8°; pulse 92.—17th: His wound was dressed to-day. There was a large quantity of perfectly sweet discharge. The drainage-tube was shortened and the sponges discontinued. Morning temperature, 98.4°; evening, 98.4°.—18th: Dressed. A large quantity of sweet discharge. Morning temperature, 98°; evening, 98.4°.—19th: Dressed. Condition unchanged. Morning temperature, 98°; evening, 98.4°.—20th: Dressed. The discharge was slightly diminished. Morning temperature, 98°; evening, 98.4°.—21st: Dressed. Discharge quite sweet. The drainage-tube is more and more extruded from the wound each day, and cannot be made to pass any further into the cavity. It was shortened to-day.—22nd: Dressed. Morning temperature, 98°; evening, 98.4°.—23rd: Dressed; discharge diminished in amount. Morning temperature, 98°; evening, 98°.—24th: Dressed. The discharge does not now amount to more than one or two ounces. The wound is looking very well. Morning temperature, 98°; evening, 98°.—25th: Dressed. There was very little discharge. The drainage-tube was shortened by about an inch. No pus came out on syringing the cavity. Morning temperature, 98.4°; evening, 98°.—28th: Dressed. About three-quarters of an inch of the drainage-tube was cut off. Morning temperature, 98°.—29th: The patient was allowed to get up.—30th: Dressed. Discharge less.

Sept. 2nd: Dressed. Spray dispensed with.—4th: Dressed. Drainage-tube shortened by half an inch. No discharge on syringing out, and very little in dressings.

The patient now gets up every day, and walks about without feeling any pain in his side. The wound is now simply a sinus, which is healing up steadily from the bottom.

Remarks by Dr. CARRINGTON.—The case seems worthy of record, both from its rapidly favorable termination, and from the fact that, in spite of the entire absence of adhesions between the liver and abdominal walls, no ill-effects ensued from the free incision of the abscess. It is the custom now at the Seamen's Hospital to freely excise all

hepatic abscesses under the carbolic spray, and it is rare to find adhesions shutting off the peritoneal cavity absent. Probably the freedom of the incisions, the large drainage-tube, the careful bandaging, and the antiseptic precautions, had much to do with the favorable issue of this case.

LIVERPOOL ROYAL INFIRMARY.

EXCISION OF A TUMOUR FROM THE STYLO-HYOID REGION; LIGATURE OF THE COMMON, EXTERNAL, AND INTERNAL CAROTID ARTERIES; ABSENCE OF INTERNAL JUGULAR VEIN; RECOVERY; SUDDEN DEATH THREE MONTHS LATER FROM DYSPNŒA; REMARKS.

(Under the care of Mr. RUSHTON PARKER.)

HENRY J—, aged forty-eight, a strong man, of previous good health, was admitted on Oct. 12th, 1880, having an ovoid tumour, about the size of a small hen's egg in the right stylo-hyoid region, apparently involving the sterno-mastoid muscle, or its sheath. There was a much smaller tumour on the opposite side in the corresponding situation, to which, however, attention was not drawn by the patient at this time. On Oct. 19th, under ether, the tumour on the right side was excised through a Y-shaped incision, with the use of the carbolic spray, and all Lister's precautions. A portion of the sterno-mastoid, but not the entire thickness of the muscle, was removed with the growth, which also involved the superior laryngeal nerve, and was intimately adherent to the sheath of the great vessels. The bifurcation of the common carotid artery was thus freely exposed, so the main vessel was tied in two places with carbolized catgut, and cut about an inch or more below its division. The internal and external carotids were similarly dealt with, about an inch above their origin, and the Y-shaped piece of vessel removed. Early in the operation the external jugular vein was doubly tied, and divided, as it was much in the way, and was moreover found to be greatly enlarged, and as thick as a correspondingly large artery. No sign of an internal jugular vein could anywhere be found.

After the operation there was a persistent cough, due, it was supposed, to the loss of his right superior laryngeal nerve; there was a subsequent distressing symptom, but there was no evidence of any disturbance of the intracranial circulation. The dressings were changed daily by the house-surgeon, who reported satisfactorily, but on the seventh, at the visit, they were found to be loose, and as the wound was thus probably exposed, they were removed, and the latter examined. The discharge was perfectly sweet, but there was a little purulent admixture; pulsation could be felt in the common carotid up to the ligature, the knot of which was exposed and wet with pus, while the stump of the vessel was also wet with pus. The wound surfaces were granulating everywhere except where a few fibrous points, also wet with pus, were seen. The stump of the vessel was now soaked in carbolic lotion, 1 in 20, and afterwards in terebene oil. Every part of the wound was freely treated with the terebene oil, 1 in 5, and sometimes 1 in 10, several times a day, the stump of the common carotid being additionally washed with carbolic lotion once a day. The upper end of the cut external jugular vein showed a plug of purple blood-clot. On the ninth day the pulsation in the tied common carotid appeared to be less distinct, and on the eleventh it had disappeared altogether. On this day the loop of the catgut ligature, white in color, was drawn away, and nothing was seen of the stump of the vessel beyond it. A purple clot could be seen plugging the artery and peeping out from the granulations.

On the eighteenth day (Nov. 6th), the remains of the ligature, two twisted black ends, that had formed the knot, came away, cicatrization advanced rapidly; and the patient was allowed to get up towards the end of the same month. He insisted on going home in December, but called and showed himself about Christmas. By this time the wound was all healed, except a small strip of granulations; its base was indurated, but whether from inflammatory swelling or commencing recurrence could not be decided.

Early in January he died suddenly, in an attack of dyspnoea, and, unfortunately, no post-mortem could be obtained.

Remarks.—Before operation the growth was judged to be a sarcoma, situated in the sheath of the sterno-mastoid muscle or in one of the deep fasciæ attached to the styloid process. A similar case had been brought to Mr. Parker by Mr. John Bark at the Stanley Hospital, where the growth was excised, in March, 1877. The wound healed, and the cicatrix remained free from recurrence; but the patient died in the following June, after an attack of jaundice and tumour of the liver. The growth proved to be a round-celled sarcoma, and the death probably resulted from secondary visceral infection and its consequences. Much light was felt to have been thrown upon the present case by the circumstances just related of the previous one; and the opinion formed was entirely confirmed by dissection and microscopical examination. The growth was also a round-celled sarcoma, and its position, in the stylo-hyoid region, one that has been the theme of much speculation with regard to congenital source and developmental causation. It is not intended here to enter upon any such hypothesis, further than to mention their existence side by side with the absence of the internal jugular vein. There was no trace of that vein between the styloid process and the middle of the common carotid artery, and of this fact there is no doubt. There was equally no trace of it in the substance or neighborhood of the tumour as examined repeatedly after removal. The great dilatation and increased thickness of the external jugular vein was at first supposed to be the result of compression and collapse of the internal jugular by the tumour; but the entire absence of that vein from the region exposed was absolutely certified by examination. Whatever there may or may not be about the tumour attributable to congenital or developmental causes, the abnormal arrangement of the great veins here has the appearance of a developmental error, of which a more exact anatomical account is unfortunately impossible, through lack of a post-mortem examination. Up to the present no record of a similar state of things in the veins of the neck has come to Mr. Parker's knowledge.

NEPAL RESIDENCY HOSPITAL.

TWO CASES OF PENETRATING WOUND OF THE ABDOMEN AND ONE OF PENETRATING WOUND OF BLADDER.

(Under the care of Brigade Surgeon Dr. J. BROWNE.)

CASE 1. Perforating Wound of Abdomen; Protrusion of Intestines; Reduction; Recovery.—Rajman, aged thirty, a healthy-looking man, was admitted into the Nepal Residency Hospital on the morning of April 3rd, 1883. He stated that on the forenoon of the previous day he was engaged in wood cutting, and when climbing up a tree with his unsheathed "kukhri" in his waistband, one of the branches on which he was supported gave way, and he fell to the ground from a distance of about twelve feet. He

was somewhat stunned by the fall; and when he came to himself he found that the "kukhri" had run into his belly for a distance of some three inches from its point and was still fixed in the wound. He withdrew the "kukhri" himself, and this act was followed by considerable hæmorrhage. At this time there was no protrusion of the viscera from the wound. He lay where he was for four hours, when, with the assistance of a boy, he with difficulty walked to his home, a distance of about one mile. The next morning he was brought to hospital; and the shaking he underwent while being carried a distance of two miles, in a "dandi," caused protrusion of a portion of the small intestine from the wound.

On admission into hospital he was at once attended to, and the following was his condition:—He was suffering from extreme shock, the result most probably of exposure and loss of blood. He complained of great thirst, and pain over the entire abdomen. His cotton cloth waistband was tightly wound round him over the wound, and was found to be firmly adherent to the protruded intestine, requiring great care in its removal. There was a transverse wound in the left side of the abdomen, about two inches and a half in length, situated midway between the umbilicus and the anterior superior spine of the ilium, and some eight inches of highly congested small intestine protruded from it. The intestine, from the surface of which blood was weeping in several places, was carefully freed from all foreign matters by gently pouring a stream of tepid water over it. When this was done, on proceeding to return the intestine a gush of bloody serum came from the wound; and the patient was now turned over on his left side, so as to favor the escape of any more fluid that might be lying in the peritoneum. By this manœuvre three or four ounces of a similar fluid came away. The intestine was reduced without any difficulty, great care being taken that no portion of it was left in the wound, and that all unnecessary fingering of the parts was avoided. The edges of the wound were brought together by three points of interrupted suture, which were inserted through the skin only, while the intervals between them were supported by adhesive plaster. The apposition of the deeper portion of the wound was effected as far as possible by raising the shoulders of the patient so as to relax the abdominal muscles. A piece of lint moistened with carbolic oil was applied over the wound, which was further supported by a compress and bandage lightly applied. For ten days the patient was in extreme danger, as he suffered from peritonitis. On one occasion only was the catheter required. The treatment employed was opium in full doses combined with calomel until the gums were affected. Hot fomentations were constantly applied. Milk, in small quantities at a time, was the only nourishment allowed for many days. On the third day he passed a healthy motion; but unfortunately, afterwards suffered from diarrhoea, which along with the peritonitis, at one time appeared likely to prove fatal. The sutures were removed on the sixth day.

This man was discharged from hospital on April 20th (seventeen days after admission), as it was absolutely necessary for him to return home. He was then convalescent, though much reduced in flesh and very weak, but his appetite was good, and he was taking soup, milk, and rice as his daily food. Rajman came to show himself at hospital on the 28th of April, and though still thin and somewhat weak, expressed himself as being in very good health in every way. The wound was quite healed up, but there was some hardness and thickening underneath it.

CASE 2. Penetrating Wound of Abdomen; Protrusion of Omentum; Permanent Entanglement; Recovery.—Urjun, a healthy-looking boy, when taking a short cut to his home on the night of the 16th April, 1883, fell from the top of a fence on a bamboo palisade, which was put up to prevent cattle from trespassing. The sharpened end of one of the pieces ran into his abdomen, and when he got up he found that he was bleeding freely, and that something was protruding from the wound. He was brought to the Residency Hospital the next morning, when, on examination, the following injury was discovered:—There was a jagged wound, an inch and a half in length, through the right rectus muscle, a little to the right of and below the umbilicus, and from it a portion of omentum, three inches by one inch, protruded. His pulse was good and he complained only of pain in and around the immediate vicinity of the wound. On introducing the forefinger it was found that the rectus muscle was freely torn, and that a portion of omentum protruded through an opening in the conjoined aponeuroses of the internal oblique and transversalis muscle, which was only of sufficient size to admit the tip of the finger by the side of the protrusion. An attempt was made to reduce a portion of omentum, but it was found that it would be impossible to do so without enlarging the opening in the posterior sheath of the rectus, and such a proceeding was, under the circumstances, considered to be neither necessary nor advisable. The protruded omentum was carefully cleansed, and a piece of lint moistened with carbolie oil was applied over it. Opium was given and fomentations were employed so long as there was any abdominal tenderness. The bowels were moved daily. There was no retention of urine. On the day of admission and the following one he had a temperature of 103°. After the third day the protruded omentum appeared to be covered with lymph, and it likewise was diminished in size. For some days he was allowed only milk as nourishment, and in small quantities at a time. This boy recovered steadily and without an unfavorable symptom. He was discharged from hospital on the 20th May, with the wound quite healed up. The protruded portion of omentum was treated as follows:—On the third day a poultice was applied over it for a few hours, and by this means the lymphic exudation was quite removed. Then finely powdered burnt alum was dusted over the surface of the protrusion, which was covered with a piece of dry lint. The burnt alum was applied daily, and on the twenty-fourth day from his admission the protruded part had quite disappeared. From this time the edges of the wound were brought together by adhesive plasters, and they rapidly united.

Remarks.—The treatment of these two cases, judging from the results obtained, appears to have been the best that could have been adopted. It will be observed that in the first case the sutures were introduced through the skin only, as I considered they would cause less irritation afterwards than if they were put in through the entire thickness of the abdominal wall and peritoneum. In one case (protrusion of small intestine) there was severe and general peritonitis, while in the other (protrusion of omentum) the peritonitis was but slight and local. In both cases opium was given with a view to control the peristaltic movements of the intestines, while in the first mercury was administered until the gums were affected. In both cases milk, in small quantities at a time, was the only nourishment allowed for days. Both cases fortunately recovered, and this result was perhaps principally due to the healthy constitutions of the patients, as well as to the close attention bestowed

on them by my hospital assistant, Mahomed Hossein, and by the dresser.

CASE 3. Perforation of Bladder through Perineum; Foreign Body removed; Recovery.—Nund Kaseer, aged seventeen, a weakly looking lad, was admitted into the Nepal Residency Hospital on March 17th, 1883. He states that eleven months previously he fell from a tree in which he was engaged cutting branches. In his fall a withered branch stump ran into him, and when his father came to his assistance he found that a piece of a branch was firmly fixed in the upper and inner part of his right thigh. The stick was so firmly fixed in the lad that it required the united force of his father and another man to pull it out, and this they did with difficulty. From that time urine passed through the wound as well as by the urethra, and the boy felt that there was still a portion of the stick in his perineum. On admission into hospital a fistulous opening was observed a little to the inside of the tuberosity of the right ischium. The opening was small, and a long probe could be passed through it for a distance of some six inches in a direction upwards, forwards, and inwards, towards the bladder. Through this sinus urine has been constantly escaping, but no foreign body in it could be felt with the probe. From the way the boy walked, with his legs widely apart, there could be little doubt that a portion of the broken stick was still in his perineum, and an examination by the rectum, and with a sound in the bladder, confirmed this opinion. The presence of a foreign body in the perineum as well as in the bladder being certain, it was determined on the following morning to cut into the perineum on the right side by making the ordinary incision of lateral lithotomy. The hospital assistant was instructed to introduce a piece of prepared sponge into the fistulous opening at once. The next morning on withdrawing the sponge it was possible to introduce a forefinger into the sinus, when, at a distance of about an inch and a half from the external opening, the end of a piece of wood was felt, which appeared to have run up between the rectum and the bladder, penetrating the latter somewhere in the vicinity of the prostate gland. With a dressing forceps, and without any difficulty, a portion of a branch measuring three inches in length and two inches in circumference was removed. This youth, when permitted to leave his bed, had completely regained his natural gait, and left the hospital on March 30th with the urinary fistula quite healed up, and the urine passing in full stream through the urethra.

BEDFORD GENERAL INFIRMARY.

RUPTURE OF BOTH LUNGS WITHOUT EXTERNAL INJURY; NECROPSY.

FOR the following interesting notes we are indebted to Mr. E. A. Laurent, M.B. Lond., resident surgeon.

J. J. B—, aged sixteen, brewer's drayman, tried to get on his cart whilst the horse was going at a smart trot; attempting which he fell, and the wheel passed over his chest. He was admitted on June 23d, an hour after the accident.

On admission, the patient was unconscious and cyanosed; a loud rattle could be heard in his throat, and dyspnoea was urgent; respiration 50; pupils equal and dilated; extremities cold; pulse of good volume, fair tension and regular (148). No marks of the wheel could be detected on the boy's garments. His jaw was firmly clenched; no blood oozed from his mouth or nose, although there was a history of his having lost a teaspoonful by the mouth. There was no ecchymosis on

the chest, and no evidence of broken or dislocated rib. Respiration abdominal; percussion note normal over left front, hyper-resonant over right. A forcible rhonchal fremitus could be felt over the left lung, and a loud, rough crepitation was heard over the whole left front, obscuring the heart sounds. The patient became restless and very violent, tossing his limbs about. A few whiffs of chloroform (one drachm) were then administered to quiet him and moderate the heart's action. The left side was strapped firmly, and a grain of ergotone was administered subcutaneously. Ice was introduced into the mouth through a gag. Patient got over the effect of the chloroform quickly, and became so restless that he had to be strapped to the bed; his breathing was more distressed. He made several attempts at vomiting, and half an ounce of bright frothy blood issued from his nose and mouth. The restlessness increased, his countenance became paler, his pulse remarkably soft and irregular, when he gave a few gasps and died, two hours and a half after the accident.

Necropsy, thirty-eight hours after death.—Temperature of room 69°; atmosphere damp. Body well nourished and muscular; cadaveric rigidity absent in arms; present in legs. Post-mortem lividity well marked in dependent parts. In mammary region a depression over the sixth rib was observed, corresponding to the buckle of the braces; over left side four discolorations, corresponding to strips of strapping, were seen. There was an ecchymosis as large as a shilling over the right internal malleolus, and another over the shin. On turning the head to one side, a large quantity of frothy decomposed blood oozed from the mouth and nostrils. An incision was made from the chin to the pubes. Some extravasated blood was found in the upper part of the pectoralis major muscles, and under the surface of the sterno-mastoid on the left side. No trace of ecchymosis could be seen corresponding to the marks on the skin. The veins of the neck were distended with blood. On opening the thorax on the right side, air was heard escaping. There was a pint of blood in the pleural cavity; a space three inches deep separated the lung from the thoracic parietes; in the groove between the upper and middle lobes was a ragged tear, three inches long, half an inch broad at its widest part, and a third of an inch in depth; and on turning up the lung along the posterior part of the root an L-shaped rent, three inches long above, one inch and a half long below, half an inch deep, and continuous with the tear along the anterior part, came into view. The right lung (weight 29½ oz.) was contused, emphysematous, and ecchymosed, the lower lobe being one mass of blood-clot; a large quantity of blood could be pressed into the bronchi. There were six ounces of blood in the left pleural cavity; the left lung (weight 32 oz.) was studded with ecchymoses from apex to base; a small slit, an inch and a quarter long and a quarter of an inch in depth, was discovered along the posterior part of the root where the lung touched the vertebral column. A good deal of emphysema was found diffused throughout, and a large quantity of blood was extravasated in the lung substance. The stomach contained four ounces of greenish fluid, and a disagreeable smell of decomposed beer was noticed; the mucous membrane was thickened; the glands and gland orifices were enlarged and mamillated. Several capillary hæmorrhages were observed here and there. The liver (weight 68 oz.) projected three inches beyond the rib cartilage, and showed under the microscope the primary cellular enlargement. The heart weighed 12½ oz. The ventricles were empty; heart substance fattily infiltrated; left ventricle hypertrophied; valves healthy. The kidneys weighed seven ounces each;

cortex thickened; glomeruli apparent; pyramids congested.

Remarks.—Rupture of the lung without any external wound, fracture, or dislocation of the ribs is certainly a rare accident. Rupture of both lungs under similar circumstances must be rarer still. The most feasible explanation of the occurrence seems to be that the deceased was young and robust, his chest walls remarkably resilient, and his lungs getting jammed against his vertebral column, the only firm and inelastic structure of the thorax, yielded at the point of maximum resistance.

SUNDERLAND INFIRMARY.

SCIRRHUS OF RECTUM; COLOTOMY; RECOVERY.

(Under the care of Mr. HOPGOOD.)

For the following notes we are indebted to Mr. J. Whitehouse, house-surgeon.

Mrs. M—, aged forty-eight years, was admitted on April 11th, with urgent symptoms arising from obstruction of the bowels.

About twelve months before admission she complained of severe pain in the left groin, which was pretty constant. About the same time she experienced difficulty in defecation, and the stools were thin and small. Her pain was not increased during defecation. She did not pass any blood per rectum. A month prior to her admission the difficulty of defecation increased rapidly, and she could get no relief from aperients, which she had been accustomed to use freely.

On admission she was in severe pain and seemed utterly prostrate. On percussion of the abdomen there was a little anterior resonance, but dulness existed everywhere else; the abdomen was extremely tense. On examination of the rectum there seemed complete obstruction to the passage of the finger three inches from the anus. The obstructing mass was hard and irregular.

On April 12th Amussat's operation was performed. The descending colon was easily found, and was much distended with feces. An hour after the operation a tremendous amount of excreta passed through the wound, giving the patient complete relief. Evening temperature 100·4°; pulse 88.—13th: Temperature normal, felt well, no sickness; evening temperature 101·6°.—15th: Had a little pain in the left inguinal region, bowels acted freely; temperature 101·4°; she was prescribed small doses of opium and aconite.—16th: Feet all right again; pulse 86, took her milk well.—19th: Wound gaped a little at its posterior extremity, otherwise looks well, union with the skin complete. After this the patient continued to improve rapidly till May 8th, when she was able to walk, and was dismissed.

Two months after the operation she was well and able to walk three miles with ease.

PRESTON AND COUNTY OF LANCASTER ROYAL INFIRMARY.

A CASE OF SPINA BIFIDA SUCCESSFULLY TREATED BY MORTON'S METHOD.

(Under the care of Dr. MARSHALL.)

For the following notes we are indebted to Mr. R. P. Forrester, senior house-surgeon.

F. G—, aged six weeks, was admitted at the end of October, 1882, with a congenital deficiency of the arches of the lower lumbar vertebrae, over which there was a tumour, oval in shape, somewhat translucent in appearance and distended with fluid. The tumour measured three inches and a

half from above downwards, and two inches and a half from side to side, and was, the child's mother said, gradually enlarging. The body was fairly well nourished, but the lower limbs were thin and paralyzed, voluntary motion being abolished and sensation impaired. The child's head was considerably enlarged, and the superficial veins of the scalp greatly congested. On the 31st the needle of a large hypodermic syringe was passed into the tumour, and between two and three drachms of the fluid were allowed to escape. Half a drachm of Morton's iodo-glycerine fluid was then injected and retained, the puncture being sealed by collodion. The operation did not appear to cause any pain.

Nov. 8th.—The swelling seemed to be unchanged. A small quantity of the fluid was withdrawn and thirty minims of Morton's fluid injected.—16th: The baby had improved in appearance, and could move its legs and feet a little. There was not much difference in the tumour. It was thought, however, to be slightly diminished. One drachm of the fluid was removed and forty minims of the solution injected.

Dec. 1st.—Removed one drachm of fluid and injected one drachm of the solution.—22nd: Tumour shrunk and flat. Skin hard and wrinkled. One small portion at upper part still thin and translucent. Head much increased in size; left side larger than right. Bones and sutures very widely separated. Superficial veins much congested. Injected forty minims.—29th: Spina bifida quite cured. Hydrocephalus still increasing. Left hospital and was not brought back.

Remarks.—This was evidently a very unfavorable case for operation, and the treatment was begun, and for a time carried on, with little hope of success; but so far as the spina bifida was concerned, the result was perfectly satisfactory.

WEST LONDON HOSPITAL.

OBLIQUE FRACTURE OF HUMERUS; COMMUNED FRACTURE OF RADIUS AND ULNA AT LOWER END; DISLOCATION OF ELBOW BACKWARDS; GANGRENE; AMPUTATION AT SHOULDER-JOINT; TETANUS; DEATH.

(Under the care of Mr. BRUCE CLARK.)

For the following notes we are indebted to Mr. W. H. Stacey, clinical assistant.

Ellen T—, aged thirty-eight, was admitted on the morning of August 12th. She had thrown herself from her bedroom window, a distance of forty feet, and had sustained an oblique fracture of the humerus about the junction of the middle and upper third, a comminuted fracture of the lower end of the radius and ulna, and dislocation backwards of the elbow. There were two small skin wounds, one at the elbow and the other on the flexor surface of the wrist. She was a woman of intemperate habits, and was drunk and very noisy at the time of admission. The dislocation was reduced with difficulty, the forearm having first been bandaged to a splint. The arm was placed on a pillow and evaporating lotions were applied. Morning temperature 99°, evening 100°4'.—13th: The patient passed a restless night; the arm much swollen. Temperature, morning 101°, evening 100°.—14th: The arm continues painful, and is much swollen; the swelling extends to the shoulder-joint. The patient rambles and shows signs of delirium tremens. Temperature, morning 102°, evening 103°4'.—15th: The arm much swollen; passed a restless night; delirium tremens much worse; fingers are commencing to be discolored. Temperature, morning 103°6', evening 102°.—16th: The fingers and forearm are quite

cold, and there is a small dark spot on the radial side; the whole arm is very tense; oedema extends over clavicular region; smell offensive. Towards the afternoon the blackness extended rapidly, as far as the elbow. The small became most offensive, and it was determined to amputate at the shoulder-joint. Temperature, morning 102°8'. 3.30 p.m.: Temperature rose to 103°2'. Under ether the arm was amputated at the shoulder-joint by transfixion; the subclavian artery being compressed there was very little hæmorrhage. The vessels were tied with carbolized catgut; the wound was washed out with carbolized acid lotion (1 in 40), a large drainage-tube inserted, and antiseptic dressings applied. The patient was rather faint and delirious after the operation, but rallied within the course of a few hours. 8.30 p.m.: There is a good deal of serous oozing; the patient is quieter. Temperature 98°.—17th, 1 p.m.: She has slept from eleven till one. Temperature 98°. 8 a.m.: She has not slept since one; fairly quiet. Temperature 102°: 1 p.m.: There is a little blood oozing from the bandage; temperature 103°4'. 3.30 p.m.: Stump dressed antiseptically. It looks well outside, and was washed with carbolic acid lotion (1 in 40), and dressed. 8 p.m.: The patient complains of feeling low, and is unable to open her jaw. The cervical muscles are in a state of contraction; she swallows liquids with difficulty; there are no twitchings; temperature 101°4'.—18th, 7 a.m.: Tetanic symptoms continue the same, with the addition that she has occasional slight spasms; she still swallows her food with difficulty. Temperature 100°4'. 11 a.m.: Still continues the same; her face presents an anxious look; temperature 103°4'. 1 p.m.: The patient complains of being sleepy; respires freely; temperature 104°. 5.30 p.m.: She has dozed a little; taken a pint of milk and a pint of beef-tea. Tetanus much the same; no spasm on taking food; pulse 142, feeble. 5.45 p.m.: A quarter of a grain of physostigma faba given. Temperature 104°2'. 8 p.m.: Rises sardonious is getting well-marked; skin perspiring freely; slight occasional spasms. Pulse weaker and rapid, 150; quite clear mentally; takes nourishment well. Temperature 105°. 10 p.m.: Pulse very feeble, 164; rambles; spasms are no worse. She has a blue appearance around the mouth; restless; is evidently failing; her extremities are becoming cold. Temperature 107°. 10.55 p.m.: Great difficulty in breathing; slight opisthotonos. Struggled and died at 11.5. Temperature in vagina immediately after death, 108°5'.

No necropsy was made on account of the rapid decomposition of the body.

KING'S COLLEGE HOSPITAL.

A CASE OF LOOSE CARTILAGE IN THE KNEE-JOINT.

(Under the care of Mr. ROYES BELL.)

For the notes of this case we are indebted to the patient, whom, with Mr. Bell, we cordially congratulate on the result.

Mr. C. S—, a medical student at King's College, received a severe kick when playing football in November, 1882, and was laid up for some weeks with synovitis of the left knee-joint. About the middle of March, owing to a fall, synovitis came on a second time, for which the knee was blistered. At this time there was an unpleasant scraping of a small, hard body above the patella. There was, however, no serious inconvenience until the middle of May, when, owing to some inexplicable cause, the loose body slipped into the knee-joint, causing intense pain and effusion. Under the influence of rest, ice, etc., the effusion subsided, and

Mr. C. S.—continued his studies until July 13th, when he entered the Fisk ward. Until this date the knee had been strapped, and Martin's india-rubber bandage was worn. The knee was also kept on a back splint. Actual operation was deferred in order not to break into the summer session studies.

On admission the limb was a little wasted, owing to want of muscular exercise. There was no effusion into the knee-joint, but in the synovial pouch which extends above and external to the patella a freely movable loose cartilage could be felt. An anæsthetic having been given by Mr. Charles Moss, the loose cartilage, which was a thin disc of the size of a broad bean, but not so thick, was removed by making a vertical incision over it, just external to the rectus femoris tendon where the tendon is expanded into the strong fascia which forms the capsule of the knee-joint. The cartilage was squeezed edgewise into the incision, caught with a pair of hooked forceps, and removed after the division of a small process of fascia, which was attached to one corner of it. The bleeding was carefully stopped; a drain of horsehair was passed into the wound, which was carefully sewn up. The operation was done under the carbolic spray, and the usual antiseptic dressings applied; the limb was also put on a splint. Two days later the wound was dressed and half the horsehair drain removed. The dressings were dry and blood-stained, as there had been some oozing of blood. There was no discharge. By the end of the week all the horsehair and stitches were removed; the wound had healed perfectly by first intention. The temperature remained normal. The patient was discharged at the end of a fortnight.

August 21st: The bandages and splint have been discontinued, and the joint has been freely used, and is in all respects as useful as the other joint.

metre, and about 4.3 white corpuscles to every 1,000 red discs. A week after her admission she was seized with palpitation; there was no fever, but the urine was found to contain a trace of albumen, and the patient died the same day. At the post-mortem examination the mesenteric glands were all enormously enlarged. The stomach was studded on its mucous aspect with numerous cream-like flattened tumours. Below the duodenum the small intestine began to be diseased. The valvula conniventes first became firmer and more swollen than usual, then polypoid and creamy lower down. The solitary glands and Peyer's patches, were enormously swollen. The spleen was greatly enlarged, but of natural shape, so that the section seemed to exhibit large Malpighian bodies throughout. The microscope showed the growths to be of lymphomatous structure. Dr. Carrington had been able to find only four similar cases recorded in the Transactions of the Society.—Mr. Hulke considered the case to be of great interest; he had never seen a similar one.—Dr. Pye-Smith referred to a case of this kind recorded by Dr. Behier about twenty years ago, which was, he believed, the earliest published case; it was an instance in which the lymphatic tissues of the intestines were enormously overgrown.—Dr. Sidney Coupland observed that Cruveilhier had figured an instance of this disease in his Atlas; this was probably the earliest case of which any note remained.

Dr. Hadden read notes of a case of Scirrhus of the Bladder. The patient was a man aged sixty-three, who was under the care of Sir Wm. Mac Cormac at St. Thomas's Hospital. The prominent symptoms which were noticed three months before admission were hæmaturia, severe pain, and dysuria. A large firm mass was felt per rectum in the position of the prostate. After death the right kidney was found to be very small. It contained a few cysts and some abscesses. Its outer surface was irregular and tuberculated. There was a soft warty-looking growth, made up of granulation tissue, attached to the mucous membrane of the bladder on the right side, just beyond the neck. The anterior wall of the bladder was much thickened, white, and very hard. The prostate was not involved. There were two or three large hard glands behind the bladder, but no other secondary deposits. The growth was of "scirrhus" nature. Although Sir Henry Thompson believes that this tumour is the most common form after villous growths, yet only two cases have been recorded in the Transactions, one by Dr. Bastian, the other by Mr. Butlin.

Mr. Geo. Lawson related the history of a case in which he had excised the eye of a child only two days old, on account of a congenital tumour of the orbit, which had completely extruded the eye from between the lids. The little patient was taken to the Royal London Ophthalmic Hospital in May, 1882, suffering from complete exophthalmos, which was congenital, and evidently due to an orbital tumour. Mr. Lawson removed the eye, and for a time the child did well. The child lived until the middle of the August following, and had been in fairly good health until within two days of its death, when convulsions came on, which were followed by coma. The post-mortem and microscopical examinations were made by Mr. Mills, the curator of the museum. The following is an abstract of his report:—A large tumour was found projecting from and filling up the right orbit. On opening the skull, the upper surface of the brain and its membranes were quite healthy. On the under surface there was a distinct impression in the right middle lobe produced by the projection of several cysts from the sphenoid bone. There was much marked basic meningitis, confined chiefly

Medical Societies.

PATHOLOGICAL SOCIETY OF LONDON.

Lympho-sarcoma of Alimentary Tract.—Tumour of Bladder.—Congenital Growth in the Orbit.—Tumours of the Brain.—Gastritis in a Bear.—Sebaceous Cyst from Finger.—Congenital Malformation of Heart.—Gumma of Dura Mater and Syringomyelia.—Rickets in the Monkey.

THE first meeting of the present session of this Society was held on Tuesday, October 16th, J. Whitaker Hulke, Esq., F.R.C.S., F.R.S., President, in the chair. The President said that he had great pleasure in presenting to the Society the thirty-fourth volume of its Transactions.

Dr. Carrington exhibited a number of specimens illustrating a malignant form of Hodgkin's Disease. The patient, a woman aged fifty-five, had died in Guy's Hospital, under the care of Dr. Goodhart. She stated that she had first noted swelling of the glands on the left side of the neck in June, 1882; in August following the legs and abdomen became swollen. When admitted, on Feb. 7th, 1883, she was very anæmic and emaciated, and the subcutaneous tissues were generally cedematous; the cervical, submaxillary, axillary, and inguinal glands were enlarged; the spleen was very large, reaching as low as the crista ili. An examination of the blood showed that there were about 4,720,000 red corpuscles to the cubic milli-

to the right side. The tumour seemed to have originated in the body of the sphenoid bone, and to have grown forwards, filling up the cavity of the orbit, and pushing the eye in front of it. The tumour was pretty solid, but contained numerous cysts in its substance. Under the microscope the tumour was found to consist of several varieties of tissue in different stages of development. The most noticeable were patches of hyaline cartilage of a spherical or oblong shape; these were often surrounded by a zone of spindle cells with a distinct gradation from cartilage cells. Numerous cysts were scattered through the tumour, of all sizes. The walls of the cyst were usually lined by pavement epithelium. In places small cysts were seen to be projecting from the walls of the larger ones. The more solid part of the tumour consisted of masses of round cells like embryonic tissue, spindle cells, and more fully developed fibrous tissue. There was evidence of formation of glandular structure at several spots. The microscopical examination showed that the tumour was evidently one of embryonic origin, with an attempt to develop into the lower forms of connective tissue and gland structure.—The President said that Virchow had described a somewhat similar case. In that case also the tumour had originated in the sphenoid bone, and was in large part cystic in structure.

Mr. Kesteven read notes of a case of Tumours of the Brain. About two years before the patient's death she had had a melanotic tumour removed from the thigh by Mr. Pearce Gould, she being then a patient of Dr. Glover's. About a year before death pain in the back and insidious paralysis of the left leg were noted. Six months before death she had a kind of "stroke," after which she was in a "tranced state" and almost speechless. Sensation was abolished, even that of the cornea. The most remarkable feature was, however, the state of rigidity in which the legs were contorted and intertwined; and the thumbs were turned into the palms. At the autopsy the meninges were found to be healthy, but on removing the dura mater a dark patch, measuring an inch and a half in the antero-posterior diameter and an inch in the transverse, was at once discovered. It was situated in and occupied the posterior two-thirds of the left superior frontal convolution, extending posteriorly to the fissure of Rolando. Below, and external to this, were seen two similar masses, smaller in bulk, and situated, the one in the middle frontal convolution, and the other in the inferior frontal. There were also similar appearances in the superior parietal lobule and in the superior occipital convolution. All these were on the left side. The first tumour mentioned extended an inch in depth inwards from the surface. A tumour was also seen in the right centrum ovale beneath the superior frontal convolution. Many nodules were found on the base of the brain; one occupied the position of the orbital surface of the left frontal lobe; another was seen about one inch below the left fissure of Sylvius. A large mass was also seen to grow from between the pons and left temporo-sphenoidal lobe; the posterior communicating and posterior cerebral arteries were embedded in this mass. Two nodules were detected in the right occipital lobe. Eleven tumours in all were recorded. Microscopical examination exhibited the structure of round-celled melanotic sarcoma. The bearing of the case on the subject of the localization of cerebral functions was discussed.

Mr. Jonathan Hutchinson, jun., narrated a case of Acute Gastro-enteritis in a Bear. The animal died, after an illness of only about a day, in February, 1883. The stomach and upper part of the

intestines were acutely inflamed. The rest of the intestines was healthy. There was no food, but much exudation, in the stomach and neighboring part of the bowel. No torulae or micro-organisms were found in it, but immense quantities of round cells and fibrin, with altered blood. The uterus, bladder, and trachea were in a state of acute catarrh. The other viscera were healthy. The wind was in the east at the time, and the probability seems to be that the disease was purely catarrhal. An interesting point was that there was no fur on the tongue.

Mr. Poland showed a Cyst removed from the flexor aspect of the ring finger of a man aged fifty-nine. The cyst had been noticed for about four years, and had become inconvenient owing to its increase in size; it was lined with layers of epidermoid cells, but there was no distinct sac; he regarded it as sebaceous.—Mr. Godlee had met with three cysts of the kind on the palmar aspect of the fingers; one measured an inch long and half an inch broad. In the third case, which had occurred recently, he had noticed a small black point, such as was commonly seen in sebaceous tumours. He, however, failed to see how the occurrence of a sebaceous cyst in such a situation could be explained.—Dr. Savage said that twenty-three years ago Mr. Bryant had removed a cyst from his forefinger, which was undoubtedly sebaceous.—Mr. Hulke said that there were several cases on record of sebaceous cysts in the anterior chamber of the eye, which had developed after penetrating wounds of the cornea involving the iris. In these cases it seemed probable that at the time of the wound some sebaceous gland had been transplanted on to the iris. This theory might explain the occurrence also of a sebaceous cyst on the flexor aspect of the finger.

Mr. Howard Tooth exhibited a specimen which presented a rare kind of Congenital Malformation of the heart. The pulmonary artery arose from the sinus of the right ventricle, and the aorta from the infundibulum; the foramen ovale was not quite closed, and the intra-ventricular septum was deficient at the base. The patient was a boy aged eight years, who died of enteric fever; cyanosis had been noticed for six years, and when admitted to St. Bartholomew's Hospital, under the care of Dr. Gee, there was, in addition to the symptoms of the enteric fever, a clubbing of the fingers and toes, a loud systolic murmur heard equally over the whole præcordia, and bulging of the chest to the left of the mesial line.

Dr. Frederick Taylor showed a case of Syringomyelus, associated with syphilitic spinal meningitis and gumma of the spinal dura mater. The patient was a woman with undoubted evidence of syphilis, who had suffered from ill-developed left hemiplegia for three years, and from paraplegia with rigidity for one year previous to death. The spinal dura mater was very much thickened throughout the greater part of the cord, and, at the level of the ninth dorsal vertebra it presented a gumma, which pressed upon the anterior surface of the cord, thereby distorting it considerably. At the same point the cord was softened, and secondary degeneration extended both upwards and downwards. Besides these changes, the cord contained a cavity which stretched nearly its whole length. The shape and lateral extent of this cavity varied at different levels. In the cervical region one section showed a cavity in each posterior cornu, the two being disconnected. There was no definite lining to the space, the wall of which merely showed the tissues of the cord in a rather dense state. This abnormal space had no connection with the central canal. Dr. Taylor had shown a similar case at the Pathological Society

four years ago, and others were recorded in German literature. A distinction must be drawn between hydro-myelus, in which the central canal is dilated, and syringo-myelus, which was the condition found in the present instance. Leyden had tried to show that the two varieties had everything else in common, and thought that syringo-myelus might arise from irregularity in the development of the central canal, especially at that stage when the canal had a T-shape, the posterior limb becoming constricted off to form the space found in syringo-myelus. Dr. Taylor was inclined to accept this explanation rather than attribute the cavity to the liquefaction of a tumour or inflammatory growth. The paraplegia was probably due to the pressure of the gumma, whilst the syringo-myelus was regarded as congenital and coincident.

Mr. Sutton said that, having had during the past summer many excellent opportunities for inquiring into the clinical history of Rickets in Monkeys, he proposed to relate certain facts bearing on that disease. The selected specimens consisted of two weeper capuchins from Brazil and a spider monkey from South America, all of them resident in the Zoological Gardens. When a monkey becomes affected with rickets, the most prominent symptoms are diminished activity and paralysis of the lower limbs, so that the creature swings himself along, using the long arms as crutches. The upper extremities then bend from the weight. Gradually the animal becomes completely paraplegic, suffers from incontinence of urine and feces; priapism is frequently observed. Death is most commonly caused by bronchitis or broncho-pneumonia. The disease advances very rapidly; in some of the more severe cases the disease runs its course in three or four months. The most interesting symptom is the paraplegia. Capuchins exhibit in an extreme degree all the characteristic signs of advanced rickets—beaded rib shafts, softened and curved bones, enlarged epiphyses and epiphyseal cartilages, deformed pelvis, etc. The skull of one specimen is remarkably eroded, perforated, and slightly thickened; on either side of the foramen magnum is a large tabetic patch. The shafts of the long bones present a very peculiar condition, for the compact tissue, instead of being arranged in the familiar concentric layers, is split into longitudinal lamellæ separated by tracts of richly cellular connective tissue, which is readily seen to be continuous with the deeper layers of the periosteum; the medullary cavities are filled with dark-red marrow. The epiphyses exhibit in the highest degree that condition to which Mr. Sutton has assigned the name "diffuse epiphysis." Further investigation has convinced him that the enlarged epiphyses met with in rickets are due to the ossific matter being deposited in a diffuse and irregular manner. In some he has counted as many as thirty in the epiphysis for the condyles of the femur. In the spider monkey the disease seems to have occurred in an older animal. The shafts of the long bones gave one the impression that new bone had been deposited in the compact tissue of a well-formed bone. The thorax was transversely deformed, due to the distension of the stomach and upward displacement of the diaphragm. The stomach was so dilated that it reached from the diaphragm to the symphysis pubis. All monkeys in whom this disease assumes severe proportions become paraplegic. He has found that this is due to gradual and slow compression of the spinal cord, the result of overgrowth encroaching upon and narrowing the spinal canal, not in one place, but general, so as to narrow the canal. Not only does the cord itself get nipped, but the nerves themselves are pinched, for the softened laminae allow the inter-

vertebral foramina to be encroached upon, due to the weight of the body. This condition explains the pain, paraplegia, incontinence, and priapism. This condition is best seen if a transverse section be made across the column, with the cord still *in situ*. In all the recorded cases of mollities ossium in man, pains, and in some paraplegia, were the leading symptoms. In all the instances in which the disease has endured for any length of time, softening of the vertebral column has been recorded whenever that portion of the skeleton has been examined at the autopsy. Pain may be due to compression of cord and nerves. The spinal cord of the monkeys presented the usual degenerations which follow on compression, from whatever cause.—Dr. Goodhart asked Mr. Sutton whether he could state the age of the monkeys; it was important to know this, because the monkeys mentioned by Mr. Sutton in his earlier communications were probably all adults; if that were so, then this affection of monkeys was analogous to that disease known as "late rickets" in man, and it was doubtful whether this was rachitic in nature. He also inquired whether lardaceous disease had been observed.—Mr. Sutton replied that there was no lardaceous disease, and said that it was extremely difficult to adjudge the age of the monkeys, as they were not born in the Zoological Gardens. The state of the epiphyses was the only guide, and this was by no means reliable.

Mr. A. Q. Silcock showed a card specimen of very extensive Ulceration of the Mucous Membrane of the lower part of the Colon, Sigmoid Flexure, and Rectum, so that only small islets of membrane with undermined edges remained. Dr. Frederick Taylor showed card specimens of Abscess of the Liver and of the Brain secondary to dysentery. Mr. Jonathan Hutchinson, jun., exhibited a card specimen of a portion of the Stomach of a Deer, which presented on its peritoneal aspect small inflammatory spots; the peritoneum also contained a small hydatid cyst, to which the spots were probably due.

CLINICAL SOCIETY OF LONDON.

Catheter Fever.—Abdominal Abscess in Children.—Cerebro-Spinal Sclerosis.

THE first meeting of the above Society was held on Friday, Oct. 12th, Sir Andrew Clark, Bart., President, in the chair. There was a good attendance of members, and two very interesting communications were read. The President congratulated the Society on reassembling at the beginning of another session. He hoped its work would result in the better treatment of disease. He asked from the surgical members of the Society information on one subject. In 1870 a man, who was otherwise in good health, consulted him for slight incontinence of urine. He consulted a specialist, who found his prostate enlarged and his bladder unable to empty itself, and advised him to use a catheter. Four days later he was taken ill; urine contained a little pus; pulse 120; temperature 100°. After two days the temperature rose higher, the pulse became more frequent, and in eight or nine days he died; the bladder was inflamed, and the kidneys were reported to be healthy. Since 1870 he had seen four or five such cases every year. He had not been able to gather sufficient information on this malady, which was not very uncommon. He was not alluding, of course, to the slight rigors after catheterism, but to a fever which generally ended fatally. The catheter had sometimes been tied in, and at others only passed occasionally.

Dr. Goodhart read notes of three Cases of Peritoneal Abscess in Children. The first was that of a girl, aged eleven years, who was said to have suffered from typhoid fever four months before she came under treatment. She was in bed for eight weeks, and in the seventh week had chicken-pox. Soon after this an abscess formed at the umbilicus and opened. She was admitted into the Evelina Hospital with a sinus discharging pus copiously at the umbilicus. She was placed under chloroform, and Mr. Howse made a thorough examination with a probe. This left no doubt, from the freedom with which it passed deeply in all directions, that the pus came from the peritoneal cavity; but, seeing that there was now no febrile disturbance, it was decided to keep the child in bed, feed her well, and watch the course of events. She steadily increased in weight, the discharge gradually diminished, and after three months had nearly ceased. She has now been for many months quite well. The second case was that of a boy, aged eleven, who had been quite well till shortly before admission. This illness, attributed to getting wet, began with rigors and vomiting. When admitted he was extremely ill, and the case was very obscure, but gradually a diffused abdominal dullness became localized in the hypogastrium and the abdominal wall began to bulge. After he had been in the hospital a month Mr. Howse made a small incision into what appeared to be an abscess. This was followed by the escape of a quantity of thin pus and some fetid gas. A long probe passed several inches in all directions into the peritoneal cavity. A quantity of fetid pus continued to discharge daily, but his condition did not improve, and the opening was therefore enlarged; but neither did this mend matters, and shortly after an explanation of its failure arose in the fact that the right pleura began to fill with fluid. The chest was incised and sixteen ounces of very fetid pus came away. Before long it became necessary to treat the left chest in the same way and with considerable relief to the child for a time. The lung, however, became consolidated, and he ultimately sank. The post-mortem examination showed that there had been a peritoneal abscess for which no cause could be discovered; that this had localized itself in each hypochondrium, and had thence perforated the pleura and on the one side had set up a destructive pneumonia. There was no evidence of any tubercular disease. The viscera were lardaceous. The third case was a female child of five years. Her illness began six weeks before admission with inflammation of the bowels, and she was sent into the hospital for supposed retention of urine, the abdominal swelling resembling a distended bladder. But the temperature was raised. So at the end of a week an exploring syringe was introduced two inches below the umbilicus, and some thick, dirty, fetid pus was withdrawn. A free incision opened a cavity which appeared to be limited behind by the intestine covered by omentum. A drainage-tube was inserted for a few days, but the discharge soon diminished so much as to allow of its withdrawal, and at the end of six weeks she was well. Dr. Goodhart thought the cases worthy of record, first, because of their rarity, and, secondly, because the question of treatment is not an easy one to determine satisfactorily. On the one hand, there is the risk of the pus gravitating to the hypochondria, as actually happened in one case, if a free opening be not made; on the other, there is the difficulty of draining the cavity of the peritoneum if it be opened freely; though, on the whole, the cases point in the direction of the latter course as being the most advisable. It is probable that the surgeon might have no doubt upon the point. He would say that free

drainage after abdominal operations presents few difficulties, and cases so treated are most successful. But it may be questioned whether the conditions after operation are quite parallel to those of pus in the peritoneum, and where there is a considerable tendency for the one collection to become distributed and to form several separate abscesses.—Sir A. Clark recounted a case in which the opposite treatment resulted well. Some three months ago he was summoned to a dignitary of the Church who had limited peritonitis, and it was thought that there was a phlegmon at the bottom of it. Soon after he became very ill with collapse and wider peritonitis. When next seen a lump was evident in the abdomen. At his third visit the swelling lying above the umbilicus fluctuated. A relative, a doctor, proposed that a surgeon should now operate; this was overruled. Three days later a quantity of pus was discharged by the rectum, and he improved. Later on again he became worse, but again pus reappeared in the stools, and since then he has steadily improved. He thought there were some cases best left to nature, and not operated upon.—Mr. R. J. Godlee had recently had a case in a child two years old, who, two months after whooping-cough, had a swelling in the abdomen, which burst and discharged first pus and then fecal matter. This went on for many months. Mr. Godlee made a free opening; the child lived about ten days, and then died. There was a cavity in front of the intestines in which were several small openings communicating with them. The glands were not enlarged. He had now at University College Hospital a baby with a small fecal fistula in the abdomen.—Dr. Mahomed thought these cases were not very rare, and he believed they tended towards recovery, and if fatal they were found to be obscure in their origin. His first case was a man admitted to hospital very ill with severe peritonitis. The abdomen was explored by Mr. Pepper, and an abscess cavity was found, partially ruptured. The peritoneal toilet was made, and wound closed, but the man quickly died. At the autopsy two abscesses were found connected with two suppurating mesenteric glands. The next case was one under the care of Mr. Davies Colley. At the autopsy no tubercle was found, but long-standing general peritonitis, with sinuses burrowing in varying directions; and openings between the bowel and abscess cavity. He quite recently had a boy, aged four, under his care with scarlet fever; he appeared to be recovering, when his temperature rose, and he became ill with peritonitis. He died on the sixth day. At the autopsy the intestines were thickly covered with creamy fluid, much matted, and collections of pus were found in the mesentery. The mesenteric glands were enlarged, but not suppurating. He suggested that in some cases irritating food or an organism excites acute inflammation in the mesenteric lymphatics, and that the disease tends towards recovery.

Mr. Howard Marsh had seen five or six of these cases. A little girl, aged six, had had some intestinal fever, possibly typhoid; this was followed by a fistula at the umbilicus. There was induration at the umbilicus, and the probe passed in here in all directions. The opening was widely dilated, and a large tube was placed in it. After about six weeks the pus was much less, and she improved considerably, and became fat and robust. He remembered, also, an infant, aged two, who had similar symptoms, with an abscess at the umbilicus, which was opened; and this case also did well. Two months ago he saw a man who, after a strain, felt a pain in the abdomen; a very large abscess formed, which was opened at the umbilicus, and afterwards another opening was made at the

right hypochondrium. But the quantity of pus was very large. After a purgative he became suddenly very collapsed, as if from perforation; he, however, got better, and two months after his return home he died suddenly in ten hours from collapse, apparently from perforation. This was one of the dangers of these abscesses. He doubted whether these cases were really tubercular.—Mr. Barker referred to a woman who, last April, was admitted to hospital with signs, it was thought, of a femoral hernia. He cut down upon the cedematous tumour, though in doubt as to its nature; he opened a very thickened sac and liberated a large quantity of pus. There was no intestine or omentum, and his finger passed freely through the femoral ring; he made a counter-opening through the abdominal wall, and drained it freely. The patient did very well. He thought all abscesses getting down towards the pelvis ought to be opened very early.—Dr. F. Taylor thought that where abscesses were recognized they should be treated as such and opened early. But as a physician he often saw cases of general peritonitis, which then became localized in abscesses. A young girl had general peritonitis, which subsided, but her temperature remained up for five or six weeks more, and then a tender spot formed in the lower part of the abdomen, which was incised; pus discharged and the case quite cleared up.—Dr. Habershon thought the cases related in the discussion were different from those described by Dr. Goodhart. They were, in fact, abscesses arising from peritonitis. In some cases there was a phlegmon in the parietes, which had a tendency to pass inwards and open in the peritoneum; and he had seen several such cases. In other cases there was a tendency to suppuration round the umbilicus in young children. Some abscesses, like Dr. Goodhart's, seem to arise from a blow.—Dr. Edis had met with cases of encysted peritoneal abscess among women. A young woman got wet and cold just before her menstrual period. A week after she was admitted under Dr. Coupland. She was very febrile and ill; pulse scarcely perceptible; great vomiting, which became stercoraceous; tongue dry. There was pain in the abdomen; the uterus was normal. Just at the "roof of pelvis" an abscess was felt, and he suggested that this should be aspirated, and he drew off twenty ounces of pus, washed the cavity out with Condy's fluid, and the patient convalesced very rapidly. He thought such cases were often overlooked, and he believed it was always well to aspirate them. He also mentioned a case of abscess which burst into the rectum.—Dr. Goodhart said that his paper referred only to peritoneal abscess in children, and in quite young children, and in them such abscesses he thought were rare. He could only find casual reference to them in literature, and then following scarlatina. He was not wedded to immediate operation when fluid was detected beneath the abdominal wall.—Sir A. Clark noted that four speakers had referred to cheesy deposits as non-tubercular, while all such deposits were generally said to be tubercular, a view which he did not share.

Dr. Charlton Bastian read an abstract of the notes of an anomalous case of Cerebro-Spinal Sclerosis. Joseph H— had been under observation at University College Hospital from time to time since the year 1877. He died on March 24th, 1882, being then sixty-two years of age. There was a neurotic history; no syphilis. In August, 1868 (then aged forty-nine), he fell down a flight of stone steps. The patient dates his illness from eighteen months after the accident, when he began to complain (1) of dragging of the left foot in walking, (2) of tingling at the tips of left fingers,

and (3) of deafness in left ear. After twelve months the first of these symptoms had disappeared; the other two remained. Four years and a half later his left leg again began to be weak. This was soon followed by weakness of the right arm and leg, and deafness on the right side. From August, 1876, he became gradually worse. He was first admitted into the hospital in October, 1877. He then suffered from paresis in all limbs; tingling in both hands; deafness and noises in both ears; giddiness; occasional headache, and pains in the eyeballs. There was no optic neuritis now or later on. There was no definite mental defect, but speech was indistinct and slow, with separate pronunciation of each syllable. Motor cranial nerves not distinctly affected. Deglutition natural. He stood and walked only with much difficulty. There was considerable rigidity of both legs, and some loss of power over the bladder. Knee-jerk present and equal on two sides. No tremors, either spontaneous or on movement, in either lower extremity. He left the hospital early in 1878, walking slightly better, but otherwise in much the same condition. Early in July, 1880, the patient was again admitted under Dr. Bastian's care. His intellect was unimpaired. Voice even more drawling and slow. Deglutition natural. The chief alterations in his condition were these:—Loss of all power of walking and of standing without assistance; loss even of power of raising feet from bed; loss of power over right hand (so that he could not feed himself or write with it as previously), with slightly increased force of grip on left side; much more paralysis of trunk muscles; the occurrence of the so-called "tache cérébrale" and of "factitious urticaria" after slight and more severe irritation respectively of skin; burning pains in trunk and limbs. The joints of the upper extremities were now rigid, and the muscles were wasted. The right leg was slightly flexed at the knee, the left extended at all joints—some rigidity on both sides. Muscles irritable to mechanical stimuli, and the interrupted current produced a tetanic condition of the muscles of the lower extremities to which it was applied. Both ankle-clonus and exaggeration of knee-jerk well marked, especially on the left side. There were still no spontaneous tremors or fibrillary twitchings in any parts, and no tremors on movement. Morning temperature often above, and evening temperature often below, the normal—99.5° and 97.5° respectively. About this time, too, the patient became more emotional, crying and laughing frequently and on slight provocation. He left the hospital at his own desire on Oct. 14th, 1880, but was again admitted under the author's care on Jan. 2nd, 1882. Still no intellectual impairment. Speech and deafness as before. Deglutition still unimpaired. Tongue protruded in straight line. No tremors. Right upper extremity rigidly flexed and motionless. On left side slight power of movement at all joints. No power of moving any part of either lower extremity. No control over fæces. Retention of urine, with dribbling and some cystitis. Breathing wholly diaphragmatic. Intercostals almost completely paralyzed. Wide-spread numbness, with diminution of sensibility. Superficial reflexes all abolished. Knee-jerk exaggerated as before. Ankle clonus easily obtained on left, absent on right side, though it returned two or three weeks later. Factitious urticaria still easily obtainable. During the next two months the patient suffered from frequent emotional disturbances—strange dreams of a terrifying nature, and many painful subjective sensations. On March 15th it was found that the patient had wasted considerably since the beginning of January. About this time his appetite

failed, his tongue became thickly furred, and his temperature rose slightly. Fresh cystitis, with blood in the urine, appeared; and bronchitis, from which he had been suffering slightly for about a month, became gradually worse. He died asphyxiated on March 25th, having been quite unable to expectorate any mucus.—Autopsy, twenty hours after death. Brain: Meninges healthy; slight amount of subarachnoid serum. On the under surface of the pons two superficial grey patches were seen. One of them, a quarter of an inch in diameter, was situated near the middle line, contiguous to the extremity of the left anterior pyramid of the medulla, which was flatter than natural, and had a greyish tinge almost uniformly throughout its substance. The right anterior pyramid on section was also found to show much grey degeneration, though less than its fellow. Sections through other parts of the medulla and through the pons showed many greyish-red patches of sclerosis, varying in diameter from a pea to a mustard seed. The root of the right auditory nerve for nearly half an inch was distinctly grey and semi-translucent. On the left side this was less marked in the superficial portion of the auditory root. The other cranial nerves were apparently healthy. The white substance of both cerebral hemispheres, but especially that of the posterior half of the left hemisphere, showed small grey areas here and there. In one section, through the region mentioned, about fifteen small patches were seen within a space of about two and a half square inches. None of them seemed to implicate the cortical grey matter. The lining membrane of the lateral ventricles was thickened, and very tough, and grey patches of discoloration were seen here and there on the surface of the thalami. On section similar patches were found through different parts of the interior of both thalami, but the corpora striata and the cerebellum were free from them. Spinal cord: Meninges healthy. Cord presenting no unnatural appearances externally. When sections were made the antero-lateral columns seemed to occupy an area relatively smaller than natural. No distinct changes of texture were recognizable by the naked eye on the cut surfaces in the eight or nine places in which sections were made. But after the cord had been immersed for some time in bichromate of ammonia, areas of degeneration were easily recognizable when fresh sections were made. A well-marked patch was seen, for instance, in the left cervical region, implicating a large portion of the lateral column, as well as a portion of the contiguous grey matter. Smaller patches also existed in this region, in the lateral column of the right side. In the lower dorsal region a distinct tract of sclerosis occupied the central portions of the posterior columns on each side of the middle line. In other portions of the dorsal, and in the lumbar regions, no very distinct patches of degeneration were seen with the naked eye, but on subsequent microscopical examination a diffuse overgrowth of connective tissue (not taking the form of limited patches or tracts) was seen in many parts of the lateral and of the posterior columns. The nerve cells, also, but especially in the lumbar region, were very notably atrophied. The central canal was enlarged throughout the whole of the cord, and densely packed with small round cells. The patches of degeneration in the medulla and other parts of the brain presented all the typical characters of areas of sclerosis in nerve tissue. Charcot, in his admirable account of "disseminated sclerosis," says:—"It rarely shows itself after thirty years. The age of forty seems, on the other hand, to be the outside limit to which patients attacked with disseminated sclerosis attain." It is worthy of note,

therefore, that in the case of J. H.—the disease first showed itself when he was over fifty years of age, and that the patient lived to attain the age of sixty-two. In regard to etiology, the only points to attract attention are—first, some evidence of a neurotic tendency; and, secondly, the fall over a flight of steps eighteen months before the first distinct signs of the disease. The arrest of the disease for four and a half years, and the symmetry of its manifestation after this date, are interesting features. Although the patches of degeneration were so numerous in the medulla and in the pons, convulsions were absent from first to last. Again, it is worthy of note that the characteristic tremors on movement which so frequently constitute a marked feature in this disease were also absent from first to last. The early weakening of cerebral control over the bladder was probably due to the existence of an extreme amount of disease in both anterior pyramids. Although the sclerosis of the anterior pyramids, and especially of that on the left side, was so marked, yet nothing like a secondary degeneration existed in either lateral column of the cord. This is in harmony with what might have been expected, since it is well known that in these patches of sclerosis the axis-cylinders are usually not destroyed, although they are more or less pressed upon and damaged. It could not be expected, therefore, that the same results would follow from a patch of sclerosis, however well developed, involving the anterior pyramids, as might be looked for from a destructive lesion (e.g., a traumatic section or a complete softening). It seems probable that the hallucinations and abnormal sensory phenomena which occurred, especially during the last few months of life, were due to the late development of patches of sclerosis in the thalami as well as in the white substance of the posterior third of each cerebral hemisphere. The power of provoking in this case, over a period of several years, both a "tache cérébrale" and "factitious urticaria" are interesting facts in themselves, and especially from the point of view of the pathogenesis of this latter condition. In regard to diagnosis, it was pointed out that in the early stages of this patient's illness all the symptoms were to be accounted for by a disease of the medulla oblongata, and that the evidence even at that time was clearly against the existence of a tumour, and in favor of disseminated sclerosis involving this region in such a way as successively to abolish the functions of the auditory nerves without interfering with the portio dura, and again of impairing the power of articulation whilst it left that of deglutition intact. The subsequent progress of the case was felt to strengthen the diagnosis of disseminated sclerosis.—Sir A. Clark asked if the vessels and kidneys were healthy.—Dr. Bastian replied that these organs were healthy.—Dr. Althaus said that Dr. Bastian had anticipated all questions by his careful and complete description. He had lately seen a case of sclerosis with absence of tremor, which was very unusual. In this case there was loss of power, nystagmus, and atrophy of the optic nerves. One of the earliest symptoms of such cases was increase of mechanical irritability of muscles.—Dr. Longhurst had traced such cases to long antecedent injury.—Dr. Money asked if the absence of implication of cerebellum and corpora striata was connected with the absence of tremor.—Dr. Bastian replied that there was no distinct nystagmus, but there was a jerking movement of the eyes. He was not disposed to accept Dr. Money's suggestion, but to explain the absence of tremor by the stress of the disease being at the first located in the anterior pyramids; which cut off the cerebral influence from the cord below. He

thought injury had much to do with the development of chronic spinal disease.

The Society then adjourned.

OPHTHALMOLOGICAL SOCIETY OF THE UNITED KINGDOM.

President's Address.—*Tubercle (?) of Choroid.*—*Tumour of Right Eye, with Right Optic Atrophy and Left Hemiplegia.*—*Glaucoma.*—*Cases of Homonymous Hemianopia.*

THIS Society met for the first time this session on Oct. 11th, Mr. Jonathan Hutchinson, F.R.S., President, in the chair. A copy of the Society's Transactions, Vol. III., was laid on the table by the President.

Mr. Hutchinson said: "In Mr. Bowman you have enjoyed the services of a president of unequalled fitness and ability—of one, indeed, who had already conferred inestimable benefits on ophthalmic science. His acceptance of the office of president at once secured the success of our infant Society, and in his recent resignation of it we have sustained a very heavy loss—one which, I am well assured, it will be quite out of my power in any degree to make you forget. It is almost certain that the Society could not have afforded to continue in these rooms and develop itself in the proposed directions had it not been helped by an act of scientific beneficence not often surpassed. Having acquainted himself with the facts, and noting our position, our late president made an offer to the Council to himself undertake the cost of purchase of all fittings necessary for the museum and library, and further, to make a gift to the Society annually for twenty years of the sum of £50, in order to defray the expenses of rent of rooms. Need I say that the Council on your behalf thankfully accepted Mr. Bowman's munificent offer? And I have now the pleasure of informing you that we are, in all probability, rent free for twenty years, and shall be able to devote the whole of our income from subscriptions to the publication of our annual volume. I am sure that you will receive this most liberal gift of your past president as one in the highest degree worthy not only of praise in the present, but of imitation in the future. The pecuniary advantages which it confers upon us are solid, extensive, and durable. But, warmly as we appreciate them, I believe I may say that those who have been most closely associated with the early years of our Society derive yet greater pleasure from the fact that one so competent to judge should in so emphatic a manner have crowned their efforts with his approbation. I have next to allude to a remarkable coincidence. Mr. Bowman's offer was made only about a month ago, and quite unexpectedly to us all, whereas for at least three months before this, and wholly unknown to him, the Council had had under consideration a proposal to recognize his pre-eminent position in respect to ophthalmology in Britain, and the invaluable services which he had already rendered to our Society. It was from Dr. Gowers that the suggestion had first come that we should found a lectureship to be known as the Bowman Lecture, but it was no sooner mentioned than it was received with unanimous approbation. This lecture will probably be an annual one, and will be delivered at a meeting specially appointed for the purpose. I cannot but think, however, that it is possible that in the future such societies as ours may find another kind of work open to them, which is only second in importance. I allude to the systematic and strenuous endeavor to diffuse

rapidly amongst the profession at large, for the prompt benefit of our patients universally, all items of new knowledge which may have been obtained. There is another branch of the same topic on which I incline, if you will permit me, to enter into a little more detail: it offers possibly a sphere for much useful work in the future on the part of societies like ours. It is one, indeed, to which perhaps this Society in particular is more specially called than any other. I refer to the promotion of what may be named every-day therapeutics. I do not doubt that there are, at the present moment, whilst I am speaking to you, in the homes, the schools, the workhouses, and the hospitals of England, some thousands of children who are suffering from ulcerations on the cornea, attended with intolerance of light, causing the patient great suffering and annoyance through many months, and destined often to leave disfiguring and incapacitating scars. If my own experience may be trusted, I believe that three-fourths of these would be almost well in the course of a fortnight under the use of a very weak yellow oxide ointment. Many of them, no doubt, are getting it, but a considerable majority probably are not; for the rule of treatment is not yet universally acknowledged amongst specialists, and certainly not very widely known in the profession. But the fact that it is meritorious in individuals to abstain from pushing their favorite remedies, only throws the duty to which I have been alluding the more definitely upon public bodies like ourselves. No one could impugn our motives or doubt our sincerity, and our verdicts would be received, not certainly as final, but as entitled, at any rate, to a temporary acceptance. I might easily mention a number of special types and forms of eye disease—purulent ophthalmia, rheumatic iritis, episcleritis, catarrhal ophthalmia, glaucoma, and the like—for which definite schemes of treatment could easily be laid down. Some years ago, in the early days of the keratome, I felt so strongly on this subject that I had some thoughts of engaging a full page in *THE LANCET* for a big red-lettered anonymous advertisement, so staring that all must read it, stating in a dozen words the symptoms and inevitable result of glaucoma, together with the certainty of its cure by operation."

Dr. George Johnson begged to propose a vote of thanks to Mr. Bowman on behalf of the Society for his munificent gift. This was seconded by Mr. Wordsworth, and carried with acclamation.

Mr. W. H. Jessop showed a girl aged twelve years, in whose family history there was a marked account of phthisis, she having also tubercular disease of both apices, especially the right. In the left eye, about the yellow spot, a round white brilliant swelling, ill-defined at the periphery, projected one millimetre. Between this swelling and the disc there were also about eight small brilliant spots. The case was regarded as one of doubtful choroidal tubercles.

Dr. J. A. Ormerod brought forward a man aged forty-four, the subject of Left Hemiplegia and Atrophy of the Right Optic Nerve. The former symptom developed first fifteen months ago; the latter appeared last May without preceding neuritis. A rounded smooth projection also existed in the upper and outer part of the right globe, detaching the retina. The patient had had syphilis ten years ago, and there was no cardiac disease or albuminuria.—Mr. Nettleship thought that the swelling in the right globe in Dr. Ormerod's case was probably due to a sarcoma of the choroid, with detachment of the retina.—In this view Mr. Adams concurred.—The case is to be submitted to a committee, composed of Messrs. Nettleship and Adams and Dr. Ormerod, for special report.

Mr. Frederick Mason, of Bath, showed a patient who had been the subject of a communication to the Society on December 8th, 1881. In this case there was a tumour at the sclero-corneal junction, which had not recurred after removal.

Mr. Pigeon exhibited for Dr. Brailey a case of Glaucoma of the Right Eye in a boy aged fourteen, following a blow from the cork of a lemonade bottle. The lens was not dislocated; but some opacities had appeared in this structure some three weeks after the accident. The instillation of eserine caused considerable improvement in the vision, and the tension of the globe diminished.

Mr. Nettleship read notes of a case of Blindness of one eye with Hemianopia of the other, due to the pressure of a tumour on the optic nerve, chiasma, and tract on the same side as the blind eye. The man came under care first in 1876, at the age of thirty, for recent failure of the left eye. The disc showed slight atrophic changes, and was said by an earlier observer to have been inflamed. Subsequently this eye became nearly blind, the disc atrophied, and the patient lost the right half of the visual field in the other eye, the disc of which also became atrophic. The hemianopia was sharply defined, and the boundary line passed through the fixation point. The left third nerve also became paralyzed. At the same time, discharge of bloody mucus from the left nostril, defective smell, difficulty in opening the jaw, and the appearance of a lump behind the jaw on the left side, pointed to a tumour at the base of the skull involving the optic nerve, and at a later stage the tract and third nerve on that side. The man died seven years after he was first seen by Mr. Nettleship, and a large tumour was found, apparently growing from the body of the sphenoid, and compressing, but not infiltrating, the parts mentioned, as well as the crus and pons.

Dr. Sharkey read a paper on a case of Homonymous Hemianopia, probably due to a cortical lesion. The patient was a female aged fifty-one, who came under Dr. Sharkey's care on July 5th, 1883. The present illness began two years and a half before whilst the patient was walking across a hayfield, when she had the first of a series of "fits" of exactly similar character. The order of events in these attacks was as follows: Suddenly there appeared "in the right eye" a play of all the colors of the rainbow "quivering" and "fluttering" before her. Then the right arm became convulsed, and the forearm and hand were rotated inwards. Soon the right leg was rigidly extended backwards and outwards; then loss of consciousness supervened, and she bit her tongue. She remained unconscious of her surroundings, and when she did recover her senses she found she had a severe pain in the top of her head and weakness of the right arm, but none of the right leg. Moreover, she could see nothing on her right side without turning her head in that direction. She had no loss of sensation or of speech. When first seen by Dr. Sharkey she had a painful area on the top of her head posteriorly about two inches in diameter, which was tender on percussion. There was weakness of the right hand and arm, and right lateral homonymous hemianopia of such a kind that there remained a considerable area of normal central vision on all sides of the fixation point. Color-vision was intact except in the blind portions. Dr. Sharkey thought that the diagnosis of a lesion of the left hemisphere affecting the cortical centre for the arm and its neighborhood was as nearly certain as any diagnosis could be, which was not subjected to the test of an autopsy. The succession of phenomena above described presented a vivid and typical picture of cortical lesions. Ferrier long ago established a

connection between each hemisphere and the opposite eye, and localized the "visual centre" in the angular gyrus. But since then Munk has proved by experiment that lesions of other parts produce, not amblyopia of the opposite eye, but homonymous hemianopia. Dr. Sharkey's case showed that in such conditions central vision may be unaltered. This being the case, it proves that there must be to some extent a separation between the area in the cortex, which receives the peripheral fibres of the corresponding halves of the retinae and that which receives the central fibres of the retina. The probabilities are in favor of the "visual centre" being an extensive expansion of grey matter in the posterior parts of the hemispheres, in which is represented separately every portion of the retinae. And probably great variety will be found in the shape of visual defects in homonymous hemianopia due to cortical lesions. In order to represent the state of our knowledge the well-known diagram of Charcot requires slight modification. Leaving in his diagram the crossed fibres as representing the central fibres only of each retina, let the neighboring but somewhat distinct cortical centre be added, from which the peripheral fibres to corresponding halves of the retinae start. From this centre draw a line running down the optic tract of its own side and bifurcating at the chiasma, one portion of the fibres passing to the periphery of the temporal half of the retina of the same side, and the other portion to the periphery of the nasal half of the opposite retina.

OBSTETRICAL SOCIETY OF LONDON.

A MEETING of the above Society was held on Oct. 3rd, Dr. Gervis, President, in the chair.

Hypertrophy of Mammar.—Dr. J. A. Mansell-Moullin showed a patient, aged eighteen, unmarried, the subject of hypertrophy of both mammar. The patient's health was otherwise good. The nipples were small, the areolae large.—Dr. Champneys had seen a case in Professor Billroth's clinic treated by rest in bed, the breasts being suspended from above.

Tumour of Clitoris.—Dr. W. A. Duncan showed a large fibro-cellular tumour involving the clitoris and both nymphæ, which he had removed.

Ruptured Ovarian Cyst.—Dr. W. A. Duncan also showed a multilocular ovarian tumour, one of the cysts of which had ruptured during an ordinary examination, leading to fatal peritonitis.—A committee was appointed to examine and report upon the specimen.

Arrested Development of one Fetus of Twins.—Dr. Edis exhibited a specimen of this kind. One fetus was born alive in the seventh month of pregnancy; the other, expelled seven hours before it, was shrivelled, and its placenta atrophied, apparently having died in utero about two months previously. Dr. Edis also showed Twin Fœtuses at about the fifth month of development.—Dr. Malins had seen a case in which one fetus had been born living at the eighth month; the growth of the other, expelled at the same time, having been arrested at the fourth month. Cruveilhier had illustrated the same condition. Such cases showed the power of toleration possessed by the uterine; and were also interesting in their medico-legal aspect.

Placenta Succenturiata.—Dr. Champneys showed a placenta succenturiata. It was impossible, from an examination of the afterbirth to diagnose the retention in utero of such a body.—Dr. Daly said these cases were of medico-legal interest. He had been called to a case in which a woman died from hæmorrhage caused by a piece of placenta left in

the uterus. An unqualified practitioner had attended to the placenta, and at the coroner's inquest pleaded that the retained piece was a supernumerary placenta, a view which was accepted by the jury.

Gangrene during Pregnancy.—Dr. Swayne related a case of gangrene occurring during the seventh month of pregnancy. The disease came on after a long journey, and attacked the integuments and muscles over a space the size of a man's fist on the upper and inner third of the right thigh. The symptoms had existed about four days before the occurrence of premature labour, but were not very severe until after delivery, when they became much intensified, and proved fatal early on the third day. There was no injury, wound, or erysipelatous inflammation to account for the occurrence.—Dr. Burchell said that, although the case was not clear, he could not help believing it to have been one of strangulated femoral hernia.—Dr. Herman asked if the case were not one of gangrenous carbuncular inflammation?—Dr. Swayne thought the most probable explanation was that the gangrene was caused by undue pressure on the iliac vessels, possibly from tight lacing, to which the patient was accustomed. The situation of the tumour precluded the idea of strangulated hernia, the vesication and absence of any head that of malignant carbuncle, and the absence of diffused redness at the onset that of erysipelas.

On the Anatomy, Physiology, and Pathology of the Os Uteri Internum.—This paper, by Dr. Henry Bennet, was then read. The author had, in 1849, drawn attention to the existence of a muscular sphincter at the os uteri internum, and this, like all sphincters, was closed when at rest. This fact was accepted by many at the time, but now seemed to have passed out of mind. It had a most important bearing on uterine therapeutics. The ordinary, physiological, closed state of this sphincter offered resistance to the passage of the metallic sound, but a small wax bougie could be passed through it. By the use of such bougies he had, in 1846, discovered that the cavity of the uterus was not straight, but had an anterior concavity. This sphincter was no doubt developed by pregnancy. It opened slightly before, during, and after menstruation, and probably during sexual congress. It was relaxed by disease, such as fibroids, chronic uterine inflammation, and endometritis. The easy passage of the sound was therefore an indication of a morbid rather than of a healthy condition of the uterus. This fact had an important bearing on the theory and treatment of sterility. If a closed os uteri were presumed to be a morbid condition, then nearly all healthy young women who were examined would be erroneously considered to require surgical treatment.—Dr. Galabin had no doubt of the existence of a sphincter at the os internum; this was shown by the constriction often seen at this point in a laminaria tent, and by the rapid contraction of the os after dilatation. But he could not agree with Dr. Bennet that it was normally completely closed. Where the passage of the ordinary sound was resisted, a smaller one without a bulbous end would often pass if the direction of the canal were hit upon, although a hitch was sometimes caused by flexion of the canal. He thought further evidence was much to be desired as to the cure of sterility by incision or dilatation of the cervix. His impression was that he had seen a larger proportion of pregnancies follow dilatation by bougies than incision. He thought it would be of great value if some of those who performed the operation would give the number of pregnancies following in a complete series of consecutive cases. The only such series he remembered did not show a greater number than might

be accounted for by coincidence.—The President remarked on the interest and value of Dr. Bennet's paper. In former years he (the President) had rarely incised the os internum. But lately, where there was evident constriction (a fact of which he had no doubt), he had done so, and his results had been distinctly better. Where the os internum was fairly patulous, and the constriction affected the os externum alone, he was satisfied with its division.—Dr. Heywood Smith protested against the use of scissors to divide the os externum, for too extensive an incision was thus made, and the power of imbibition possessed by the external os destroyed. The most scientific method of doing the operation was with Sims's narrow-bladed knife.—Dr. Playfair believed very little in stenosis of the os internum, and not at all in its incision for the cure of sterility. Incision of the os externum in well-selected cases was occasionally followed by pregnancy, but he believed it was done far too often and too indiscriminately. He believed it acted not only by enlarging the os, but by remedying the conical condition of the cervix, which was more often than stenosis the cause of sterility.—Dr. Champneys pointed out that difficulty in the passage of the sound was not proof of stenosis of the os internum. Difficulty might arise, even when the canal was larger than usual, from the instrument being passed in the wrong axis, or from its point catching in a fold of mucous membrane. It was only when the bulb of the sound was gripped during withdrawal that stenosis could be inferred.—Dr. Aveling was sure that contraction of the os internum was a cause of dysmenorrhœa and sterility, and believed that incision gave more permanent relief than dilatation. After incision he did not use a stem pessary, but passed the sound daily for a week, and then less often, till healing had taken place.—Dr. Edis thought there were instances in which division of the internal as well as the external os was needed. Each case must be treated on its own merits, it being impossible to lay down any general rule. After incision he used a stem pessary, the patient being carefully watched.—Dr. Murray thought division of the os uteri for sterility alone of doubtful utility. He had seen many cases in which it had been done without good results. It was not free from risk to life, and ought not to be done simply at the request of the patient.—Dr. Henry Bennet gathered that his views were generally accepted, although some might not go as far as he did. Deep division of the cervix had been formerly, and he believed was still, too frequently performed by some practitioners. The abuse of surgical treatment might be on the wane in England, but certainly was not elsewhere. It was therefore desirable to establish the anatomy, physiology, and pathology of the os internum on a sound basis. Other waves of opinion were setting in, equally exaggerated in their character; as, for instance, in America, the unjustifiable sewing up of the lacerated cervix uteri for insignificant lesions, easily cured by the simplest local treatment, and with us the abuse of pessaries.

LIVERPOOL MEDICAL INSTITUTION.

A MEETING of this Society was held on Oct. 11th, Mr. T. Shadford Walker, President, in the chair.

The customary conversazione at the opening meeting was limited this year to an exhibition of frozen sections of the human body and a collection of skulls and teeth from the Medical School. The former, prepared by Dr. Barrow and his assistant demonstrators, proved very attrac-

tive, for after being cut and hardened in spirit the sections had been allowed to dry slightly, and the various tissues then colored with oil paint. They were mounted in spirit in large basins with flat glass tops, and were fixed in tinted plaster-of-Paris, the result being very effective. Some of the sections had been sketched in water-colors by Mr Dixon, a senior student, the structures being all lettered and named, and corresponding letters being placed on the same structures in the sections. When all are completed in this way they are to be put in the dissecting-room. The skulls and teeth had been collected and prepared by Mr. Paul for the dental department of the school.

When the above specimens had been viewed, the President opened the session with a few introductory remarks, and the ordinary business was proceeded with.

Multiple Sarcoma.—Dr. Carter showed the internal organs of a man aged twenty-two. The following is the history of the case. Three months ago he noticed two small lumps in the skin above the umbilicus. Shortly several others appeared; and when first seen, two months subsequently, there were thirty or forty over the trunk, but only one on the limbs. At the same time vomiting and jaundice came on, with progressive debility and hæmatemesis, till he sank and died. At the post-mortem examination a large mass of a soft sarcomatous appearance involved the pancreas, and another smaller mass infiltrated the root of the left lung, and the neighboring thoracic and abdominal glands were affected. There were numerous nodules of small size in the liver and kidneys, and a rather large mass occupying the left adrenal. The deposits beneath the skin had the same appearance as those in the internal organs. Dr. Carter thought the mass in the pancreas to be the oldest. The growth was a round-celled sarcoma.

Tumour of the Medulla.—Dr. Glynn read the history of a middle-aged man, who had contracted syphilis fourteen years ago, and was recently admitted with headache, vomiting, and hiccough. Shortly, there supervened numbness and loss of power on the left side and of the lips, paralysis of one vocal cord, and external strabismus. He was subject to what he called weak fits. Subsequently he became ataxic and salivated; but the reflexes and taste were normal. Optic neuritis became marked, and temperature high. No sugar in the urine. When raised in bed he was attacked with epileptic seizures. At the post-mortem a tumour was found occupying the restiform body below the level of the floor of the fourth ventricle, and extending through the medulla to the olivary nucleus. It involved the nuclei of the pneumogastric and hypoglossal nerves, and part of the long nucleus of the fifth.

Ligature of the Brachial for Wound of the Palm.—Mr. Puzey read a short paper on this subject, based upon two cases in which a high division of the brachial was found. In each there had been several hæmorrhages, and the operation was only adopted when the symptoms became urgent. In the first case, an incision having been made over the brachial in the middle of the arm, a large artery was met with, upon ligature of which pulsation in the ulnar alone ceased. Further exploration discovered another similar vessel, which proved to be the radial. In the second case ligature of the main artery in the position of the brachial stopped pulsation in the radial, and lessened it in the ulnar. During the operation a large vessel, supposed to be the inferior profunda, was turned aside. Mr. Puzey subsequently believed this to be a high ulnar, and upon recur-

rence of hæmorrhage three days later he ligatured the ulnar at the wrist, after which recovery took place. From his experience of these cases, Mr. Puzey recommended that ligature of the brachial should be resorted to much earlier than was the usual custom for hæmorrhage from the palm.—In the discussion which followed, Mr. Mitchell Banks considered that in a fresh wound of the palm the bleeding vessel should if possible be ligatured, but that in older wounds the brachial should at once be tied upon the occurrence of secondary hæmorrhage.—Mr. Rushton Parker and Dr. Alexander advised ligature at the spot if the superficial arch were wounded, but compression in the case of the deep arch.—Dr. Macfie Campbell and Dr. Barrow criticised the anatomy of the high division of the brachial.—Mr. Paul had found that in punctured wounds treated by compression in which secondary hæmorrhage had taken place there was usually a small false aneurism. He thought that it was rather this condition which prevented closure of the artery than any process of sloughing or ulceration, and, with antiseptic precautions, recommended ligature of the vessel at the injured part under all circumstances.

ACADEMY OF MEDICINE IN IRELAND.

At a recent meeting of the Surgical Section, a paper was read by Mr. Thornley Stoker, on Removal of the Thyroid Gland in Cases of Bronchocele. He detailed the case of a boy on whom he had himself operated, the disease being the most extensive of which he could find any operative record. The tumour extended nearly from ear to ear and hung down nearly as low as the navel. He removed two-thirds of the mass, comprising the right lobe and isthmus, in March, 1882, and the remainder, on the left side, a year later. Complete recovery followed the first operation; but the patient died five days subsequent to the second, from pulmonary thrombosis. He was incompletely cretinish, but developed greatly after the first operation. Mr. Stoker considered that the ablation of the thyroid gland for disease should be held justifiable, the patient so desiring, not only in cases where the disease threatened life, but where discomfort or disfigurement existed and minor treatment had failed.—Dr. R. McDonnell said he was present on both occasions. The first operation might be regarded as quite successful, and taught the lesson that in cases of the kind the operation was justifiable. The second had a fatal issue, from a cause not necessarily connected with the operation.—Mr. Corley stated that in his hospital practice some years ago a similar case arose, where the pressure of a large thyroid gland became so great as to render operative interference necessary. He did not think Mr. Stoker had placed sufficient emphasis on the magnitude of the operation.—Dr. H. Kennedy drew attention to the treatment of thyroid tumours by the seton, and mentioned a case in which at the end of some months the disease was entirely cured. Such a measure as that would be more justifiable in the first instance than the terrific operation described by Mr. Stoker.—Mr. Thompson thought, whatever use the seton might be in some cases of small thyroid tumour, it would have been useless in Mr. Stoker's case, in which the vessels were of enormous size.—Surgeon-Major Hamilton remarked that 10 or 15 per cent. of the population in the Himalaya valleys suffered from bronchocele. Sometimes twenty or thirty coolies might be seen climbing mountains 2000 to 3000 ft. high, carrying heavy loads, 50 lb. or 60 lb. in weight, and

each having a tumour. Rubbing in biniodide of mercury ointment with a spatula as they lay on their backs in the sun always relieved. The great benefit seemed to be derived from doing it in the sun. He had seen many cases so treated, and had not known any of the men to die from it. In the Himalaya valleys syphilis was supposed to be the cause, and the people lived on inferior food in overcrowded, dirty, and badly ventilated houses.—Dr. Foy instanced the case of a woman, aged twenty-two, who had a very rapidly growing thyroid tumour, which caused her inconvenience both in breathing and swallowing. It became urgently necessary to do something, and he applied a blister on the back of the neck with the best result. A seton was subsequently inserted, and the gland in a short time assumed its normal size.—Mr. Stokes endorsed what Mr. Stoker had said regarding the inutility of using any mild measures in such cases as he had described; but in those referred to by Dr. Kennedy, Dr. Foy, and Surgeon-Major Hamilton, the tumours were probably of extremely simple structure. He recollected two cases in which merely tapping, followed by a weak solution of tincture of iodine, sufficed. The employment of setons found little favor in his eyes. In Mr. Stoker's case nothing short of the very heroically performed operation adopted would have given the patient the slightest chance of recovery. The introduction of air into the veins was avoided by the application of the double ligature and dividing the veins between them.—Dr. Bennett did not suppose any surgeon would propose to operate, knowing that if the epidemic influence, or the particular exciting cause, such as pregnancy or menstruation, was past, the tumour, troublesome and dangerous at the time, would become quiescent or even disappear. The point that struck him as difficult of explanation was, how it was possible to make the tumour disappear by biniodide of mercury. It would be interesting to know whether such treatment was successful in the case of Europeans in India, or was the success confined entirely to the natives? He was inclined to think, however, that the result of exposing a European to the sun for a sufficient time to cure him of the goitre would be to kill him. The great desideratum was to diagnose exactly the kind of tumour that ought to be the subject of removal.—Surgeon-Major Hamilton observed that it was the smaller tumours which were often radically cured. Europeans were treated for enlargement of the glands the same as the natives. The only danger was from sunstroke, but this was avoided by placing the upper portions of the body in the shade.—Mr. William Stoker mentioned that similar treatment was the rule in Switzerland.—Mr. Wheeler said that no one would think of extirpating the thyroid gland for enlargement due to anemia, or the thyroid enlargement of menstruation, or what might be termed the cystic bronchocele; but he was of opinion that bronchoceles of large size, and when very chronic, if causing dyspepsia, dysphagia, pressure on the jugular vein, or vertigo, ought certainly to be removed. He did not think that the rays of the sun were essential to act on the biniodide ointment; the heat of the fire would answer very well.

Mr. Swan read a paper on the Primary Consideration of Orthopædic Cases. He explained certain allusions to affections not strictly to be termed orthopædic by stating that they very frequently were seen by surgeons practicing that branch of surgery. From a prolonged observation of a limited number of examples made by himself, and from the results obtained from the records of Dr. H. Cuthbertson and Dr. Virgil Gibney, of New York, he arrived at the following conclusions:—

(1) That the advantages of excision or evitement in tarsal caries do not appear to be so obvious as to warrant their frequent application; (2) that, as there is no evidence of amyloid degeneration of viscera in long-continued suppuration of the tarsal joints, conservatism in its widest signification may be specially applied to disease of this structure; (3) that an anchylosis of the tarsal articulations, a result of the generation of plastic material during the course of the disease, will occur, but that this process, though diminishing the mobility of the foot, will leave it fairly useful. In referring to angular curvature of the spine, the impossibility of predicting the amount of deformity was maintained. The supervention of paraplegia, on the other hand, might be confidently anticipated to occur only in caries of the cervical or upper dorsal vertebrae. So far as the paralysis was concerned, the prognosis might be stated to be usually favorable. The probability of the development of abscess was shown to be chiefly the results of motion, and not necessarily the sequence of extensive gibbosity, or even extensive implication of tissue. Scoliosis was stated to be, except in an early stage, an incurable affection. In equinovarus section of all resisting structures was insisted on, and relapses were said to be often due to a neglect of this rule. Mere congenital distortions of the feet were divided into—(1) those the result of nervous lesions; (2) those depending on ligamentous relaxations; (3) neuro-mimetic affections; and (4) those of traumatic origin. In the treatment of deformities of the lower limbs depending on essential paralysis as usually adopted, whether by counter irritation, localized galvanism of Duchenne, massage, or the Swedish movement cure, the writer did not put much faith, but held a strong opinion on the utility of the direction of volition to the limb, while by proper means maintaining symmetry, holding that the development of the use of the unaffected muscles even remotely attached to the member established a compensating power and believing that in many cases some of the fibrillæ of muscles, the bulk of which were paralyzed, retained contractile power.—Mr. Wheeler was of opinion that Mr. Swan was not sufficiently explicit in his paper with reference to the disease of bones of the foot, and the excision of bones, etc. A tolerably acute diagnosis of the extent of the disease could be formed by observing where the disease commenced. There were four distinct synovial sacs in the foot. Hence it would be easily understood that the extent of the disease would be greatly influenced by its starting-point. Complete excision of the os calcis was not a common operation. The results in two cases he had were most satisfactory; a third, however, was not quite so successful. He deprecated the use of the gouge as a dangerous and unscientific practice, especially in disease of the ankle-joint.—The President remarked that the partial removal of carious bone was exceedingly unsatisfactory. Although Mr. Wheeler had condemned gouging, his experience of it had been attended with marked success.—Mr. Swan replied.

At a recent meeting of the Medical Section, Mr. Stokes read a paper on the Therapeutic Value of Nerve-stretching in *Tabes Dorsalis*. He commenced by pointing out that the evidence afforded by the cases of *tabes dorsalis* treated by nerve-stretching indicated the fact that relief from some of the most distressing symptoms of that disease may, if the operation be performed sufficiently early, be anticipated. He considered that the absence of a physiological explanation as to how the operation acts is no reason for its rejection, and

gave instances of other operative procedures of which the *modus operandi* is as yet unexplained. The particulars of two well-marked examples of the disease treated by him, in one of which he stretched the sciatic nerve on one side, and in the other on both sides, were then given. Although the operations were not followed by any signal improvement in motor power, the results in other respects, as regards relief from lightning pains and vesical irritability, and return of sensibility in certain regions of anæsthesia were satisfactory and encouraging. Then Mr. Stokes discussed the importance of estimating accurately the amount of force that should be used, and was of opinion that a very moderate amount is sufficient to obtain the desired therapeutic results. He also stated his belief that many of the recorded failures of the operation were to be attributed to the employment by the surgeon of an undue amount of force. He advocated the use of an electric cord and dynamometer in nerve-stretching, and believed that in the case of the larger nerves a force of about 10 lb. would be found sufficient.—The President did not see why they should pass over nerve-stretching merely because they did not understand the *rationale* of the treatment. He thought the procedure would apply to nervous functional affections, such as sciatica.—Dr. Duffy said there was no doubt that the operation gave a certain amount of relief to some of the distressing symptoms of the disease. Ceccherelli, in giving an analysis of 100 cases of nerve-stretching for various conditions, had described certain pathological changes where the operation had been followed by extravasations or regenerative changes affecting the vessels of the nerves, which, he presumed, tended to diminish the sense of conductivity of the nerve. The amount of traction was so great as to affect the cord directly. Some observers believed in certain changes having taken place in the cord itself. In favor of this view nerve-stretching on one side of the body might relieve symptoms referable to both sides.—Dr. C. J. Nixon considered that the operation of nerve-stretching in this disease should only be used in desperate cases, after all other means of giving relief had failed.—Dr. H. Kennedy thought that slightly pinching the nerve, and thus conveying irritation that could not injure its substance, might have a beneficial effect.

Dr. McSwiney read the notes of a fatal case of Thoracic Aneurism occurring in a sailor, who had worked at his employment up to within one month of his death. The aneurism was not diagnosed during life, as there were no signs or symptoms present specially characteristic of the disease. The man was supposed to have got cold from exposure during bad weather. He had cough, bronchial rales, and pain in the region of the heart. Physical examination threw no light on the nature of the case. The patient expectorated nine or ten ounces of bright-red blood and died in a few hours afterwards. At the necropsy the aneurism was found to spring from the posterior and outer aspect of the descending portion of the arch of the aorta, and to project into the upper and inner parts of the left division of the thorax, a portion extending across the vertebral column, eroding the bodies of the third, fourth, fifth, and the upper part of the sixth dorsal vertebrae, and lying in the upper and inner portion of the right division of the thorax. The third and fourth ribs on the left side had been eroded, and the tumour had passed backwards between them a short distance. The entrance into the aneurism was about as large as a sixpence, and a quarter of an inch below it a little pouch was formed in the site of the origins of the first pair of intercostal arteries.

This was evidently the beginning of a second aneurism, the aorta being in this position very much diseased. The arch and thoracic portion of the aorta were atheromatous, as were all the valves of the heart in varying degrees. The bronchi and œsophagus showed no signs of pressure. The thoracic duct could not be found, but large lymphatic vessels connected with glands lying at the sides of the dorsal vertebrae were to be seen. The sac was filled with laminated fibrine, and was covered with a quantity of tough matted tissue. The aneurism was therefore diffused. A few fibrous strings were to be seen at the upper portion of the pericardium, but no signs of pericarditis on any other portion of the pericardium. The lower lobe of the left lung at its superior posterior part had become adherent to the aneurism, which had here burst into it. There was a cavity in the central portion of the external part of the lobe, which was covered only by pleura. The costal pleura was thickened on both sides, and on that portion nearest the tumour the deposited lymph had undergone fatty degeneration.—The President could not agree that symptoms were quite absent.—Dr. Finney drew attention to the absence of hypertrophy of the left ventricle, notwithstanding the size of the aneurism, which confirmed Stokes's observation on this point.—Dr. C. J. Nixon related a similar case of fatal aneurism, in which the only symptoms present during life were those of severe bronchitis.

At a meeting of the Pathological Section, held on May 4th, the following living specimens were exhibited:—Dr. J. S. McArdle: Deformity of the Upper Extremity and Arrest of Development following Injury of the Median Nerve. Mr. Benson: Nyctalopic Conjunctivitis. Mr. Coppinger: a patient suffering from Hydatid Disease of the Femur.

The following specimens were exhibited by card:—Mr. Abraham: Ulcerations of the Intestines associated with Malignant Disease of the Cæcum, with microscopic mountings. Mr. Coppinger: Portions of Bone affected by Hydatid, removed from the Femur of the patient exhibited. Mr. Stoker: Thrombus of the Pulmonary Artery. Mr. Abraham: a single Kidney from the body of a man; the Left Kidney, with its vessels and ureter congenitally absent. Dr. L. Maturin: (1) Congenital Deformity of the Forearm and Hand; (2) Aneurism of the Ascending Aorta. Mr. Corley: Impacted Alimentary Bolus.

Dr. E. H. Bennett read a paper describing the characteristics of a Congenital Malformation of the Thorax, in which the anterior extremities of a single rib failed to reach its cartilage, and there existed, in consequence, a depression of the thoracic wall on one side, while the cartilages attached to the corresponding part of the opposite side were hypertrophied, and projected as tumours in front of the level of the sternum. Having referred to the description of this malformation given by Otto and Rokitsky, in which no mention is made of excessive development on the side opposite to the defect, Dr. Bennett showed a preparation which presented the characters mentioned in a most marked degree. He pointed out the importance of a knowledge of this malformation in relation to diagnosis of lesions of the costal cartilages, illustrating the point by the facts of the case from which he had obtained the specimen, and from two other clinical observations. In all three cases injuries had occurred, which suggested that the thorax had been crushed, and the diagnosis had been erroneous in one, that from which the specimen exhibited had been taken.

The Secretary (Dr. Bennett) read for Mr. J. Davidson a paper on the Influence of Fracture on the

Growth of Bone, in which the author recorded the results of his observations on the fracture of the long bones of the lower animals, chiefly fowls, in which the injury occurred during the active growth of bone. Comparison of the injured bones with their fellows showed that there existed a marked increase of size in all dimensions, the bones being heavier and longer on the fractured side.

Drs. Fraser, Stoker, Corley, McSwiney, Bennett, and Abraham discussed the foregoing paper, and expressed their sense of the exactness and care displayed by the author in his investigation.

Dr. Coppinger read a paper on Hydatid Disease of the Femur, the patient and parts removed which established the diagnosis having been exhibited to the meeting already. He alluded to the infrequency of the occurrence of hydatid tumours in the human subject in Ireland, notwithstanding the known prevalence of the echinococcus disease in sheep. He observed that hydatid tumours, even in countries where the affection is comparatively common, seemed scarcely ever to invade the bones, and that no instance of the disease occurring in the bones had up to the present been recorded in this country. The patient had been under observation for three years, having been admitted to the Mater Misericordiae Hospital with a spontaneous fracture of the upper third of the femur, due apparently to its invasion by the parasite. The disease was not diagnosed until Mr. Coppinger had made an attempt to excise the patient's hip-joint and discovered a large cavity in the dilated upper part of the femur containing hydatid cysts and loose pieces of bone studded over with small echinococcus vesicles; these exhibited the characteristic features of echinococcus cysts, etc. The complicated excision was abandoned, but the great trochanter was removed with a saw, and the cavity finally laid open and syringed out with chloride of lime solution. It was then ascertained that the shaft of the femur was firmly connected with its neck by means of the thin walls of the bony tumour, and it was hoped that the disease having been apparently removed the space would fill by granulation from below; it had since become much smaller; but the patient's condition was so unsatisfactory, even after nearly two years' treatment, that another operation would have to be performed for the purpose, if possible, of eradicating the disease. The limb was three inches shorter than its fellow. The man was obliged to have a crutch, being unable to rest his weight upon the limb; and the wound, which was still open, led through a narrow slit in the bone into a cavity in its centre, extending upwards into the neck as well as downwards into the shaft of the femur. Although this cavity was daily washed out with carbolic and boro-glyceride solution, and although all disease was apparently removed, collapsed cysts and shreds of membrane still escaped from it occasionally, proving that the peculiar disease caused by the presence of small exogenous cysts in the cancellous tissue of the bone had not yet been eradicated.

Mr. Thornley Stoker read notes of a case of Thrombosis of the Pulmonary Artery occurring in a boy subsequently to the removal of the thyroid body, and proving fatal. He exhibited the specimen.—Dr. Bennett expressed his doubt as to the character of the thrombus, regarding it as a post-mortem production.—A discussion followed, in which Drs. Thompson, Corley, Kidd, and Abraham took part; and Mr. Stoker replied.

Dr. R. A. Hayes exhibited on a screen with the lantern photographs of the microscopic appearances of normal and diseased tissues, and explained the details of the process.

The Section adjourned.

At a meeting of the Medical Section, held on May 18th, the following living specimens were exhibited:—Dr. J. C. Nixon: Case of Aortic Aneurism, with patency of aortic valves; anomalous physical signs. Mr. Coppinger: A Case of Paralysis following gunshot wound of the spinal cord.

The following specimen was exhibited by card:—Dr. J. Magee Finny: Nodose condition of the Hairs.

Dr. John B. Story read a paper recording three cases of Exophthalmic Goitre. The cases occurred in three women, two of them being unmarried. The following were the points of interest. Two of the patients were sisters, and the third exhibited the remarkable, and probably unique, complication of double optic neuritis, which, however, had subsided at the time the patient came under observation. In this patient the goitre was more marked on the left side, and the palpitations did not occur until five years after the goitre and exophthalmos; in the other two, the goitre and exophthalmos were more marked on the right side, and the palpitations were the earliest symptoms observed. Mr. Story called attention to the support these three cases gave to the theory propounded by Dr. William FitzGerald in the *Dublin Journal of March and April, 1883*.—The President said that although the disease was almost peculiar to females, he recollected three cases in which it occurred in males, the course being short, not quite eighteen months. On the other hand, he had seen it run on for eight or ten years in females. To him the disease appeared to be of neurotic origin.

Dr. Walter Smith related a case in which he had successfully removed a small Polypus from the right vocal cord of a lady aged thirty years by Voltolini's sponge abrasion method. About Christmas, 1881, loss of singing voice came on. This was followed by hoarseness, which persisted for a year. In December, 1882, the patient consulted Dr. Smith, who recognized the existence of a pale-red pyramidal tumour attached to the edge and lower surface of the anterior third of the right vocal cord. After a short preliminary training, he succeeded in passing a moistened sponge about the size of a hazel nut beyond the growth, and then forcibly withdrawing the sponge through the rima, and bearing towards the right side, was fortunate enough to detach the little tumour, which came up adherent to the sponge, and was preserved. Immediately after the operation voice was restored, the hoarseness had disappeared, and the patient was able to sing. Six weeks subsequently she reported herself as perfectly clear in voice. The operation is a safe and painless one, and suited to a limited number of cases.—Dr. Beatty remarked that the attachment of the tumour to the under part of the vocal cords favored its removal by Voltolini's method. He had met another case in which, owing to its position anteriorly, this method failed.

Dr. Henry Kennedy read a paper on some of the forms of Dilatation of the Colon. The condition of the patients who had this affection was always that of impaired health. With this state, when the patients, who were usually thin, were examined lying on their backs, there was chronic tympany, though not necessarily to a great degree. Pressure on the abdomen did not cause pain. In conjunction with these symptoms the author stated that the main characteristics of the disease were the faecal discharges, always dark, pasty, and unformed. He insisted particularly on the persistence of such discharges for weeks, months, and even years, during which periods the patients were constantly subject to attacks of diarrhoea,

acute or chronic, and were liable even to perforation of the bowel and rapid death. He considered the prognosis should always be guarded. Treatment could much benefit those cases; but he doubted whether a complete cure could be effected.—Dr. Gunn asked if electricity had been tried, and quoted a case of atonic condition of the large bowel in which it seemed to have proved of benefit.—Dr. Finny, too, bore testimony to the great advantages of galvanism applied by a rectal rheophore in cases of atony of the bowels.—Dr. Walter Smith said it should be remembered that there were great difficulties in applying any anatomical rules to the living subject, deduced from the position of parts of the dead body.—Dr. H. Kennedy, in reply, said he did not use electricity in any of his cases, nor had he made any post-mortem examination.

The President congratulated the Section on the success of its first session, which had now come to a close.

Editorial.

THE SEARCH FOR THE CHOLERA GERM.

WHATEVER value may ultimately be assigned to the discovery by Dr. Koch of the presence in the intestines in cholera of a definite kind of bacillus, such a discovery is, it must be admitted, a substantial advance upon previous knowledge. It is moreover an advance in the very direction to which all the known facts of the disease point; for whether the conditions of its origin be regarded, or the manner of its spread, cholera has undoubtedly with good reason been held to depend upon the presence of a specific organized virus. There are indeed few diseases to which the germ theory is more applicable. But just as has been the case with many of the infective diseases (in some of which the truth of the theory has received striking confirmation), the hypothesis which is put forward to explain the phenomena of the affection is in advance of actual fact. When, however, we find good proof of the existence of an organized virus in malarial fevers, and in relapsing fever, we cannot deem it at all beyond the range of probability that some day similar facts will be discovered in regard to cholera, the nature of which is apparently more clearly related to the great group of specific infective diseases than is either of these two affections.

The search for the presence of a micro-organism that could be proved to be possessed of the specific qualities of the cholera virus was the main object that Dr. Koch and his colleagues had in view. They arrived in Alexandria when the epidemic, which was never very severe in that city, was already on the wane; and the total number of cholera cases examined by them amounted to twelve only observed during the progress of the disease, and ten which were examined after death. Nothing distinctive was found in the blood, nor in those viscera which are usually the seat of specific micro-organisms—as the liver, lungs, and

spleen; the organisms that were found in the vomited matters, and in the alvine evacuations, were not distinctive; but the search in the intestinal walls revealed uniformly and invariably the presence of a rod-shaped bacterium or bacillus, much resembling the glanders-bacillus. The micro-organism occurred chiefly in the lower part of the small intestine, in and beneath the epithelial lining, within the tubular glands and villi. Its presence excited inflammatory changes in the glands, and in severe cases hæmorrhage in the submucous tissue. Ten years ago a similar search was made in India by Messrs. Lewis and Cunningham, but with less positive result. No special form of bacterium rewarded their efforts. Dr. Koch in his report mentions that a year ago he had detected this bacillus in specimens sent to him from India, but being unable to exclude the possibility of putrefactive changes in these specimens, he had not laid much stress on the fact, preferring to wait until, as has now happened, opportunity should be given him of conducting the examination free from all possibility of error on this score. It may be remembered that Messrs. Lewis and Cunningham observed peculiar changes in the protoplasm of the blood. They also experimented largely by inoculation of lower animals with the alvine discharges of cholera patients; but the result of their labors did not determine the existence of a special virus, for their inoculation experiments did not reproduce cholera in the animals, but a form of hæmorrhagic enteritis, similar to that induced by inoculation with non-choleraic evacuations. Indeed, on this very point of the transmissibility of cholera to lower animals—the key-stone of the proof of its specifically infective nature—Dr. Koch has been no more successful than his forerunners. He, too, has failed to reproduce cholera in the animals experimented upon, including mice (to which Thiersch is said to have succeeded in giving cholera) and monkeys. Proceeding according to his well-tried method, Dr. Koch succeeded in isolating the bacillus met with in the intestine, and in cultivating it outside the body. But all the further experiments by feeding and by inoculation failed to transmit the disease, and therefore to establish a proof that the bacillus in question was the virus of which he was in search.

It will be unfortunate for the sake of the value of this discovery if the lower animals be proved to enjoy an entire immunity, and therefore it is with some relief that we find Dr. Koch affording an explanation of his failures which has sufficient probability in it to justify the German Government in sanctioning his further research in India. He points out that the virus had already lost much of its power; the epidemic was subsiding, and the immunity enjoyed by the animals might really be due to the same cause as was conferring immunity upon the human inhabitants of Alexandria. He argued, and with justice, that more fruitful results

might follow if he could deal with cases occurring in an epidemic that was still at its height, and he wished to proceed to some of the villages where he could prosecute his researches under such conditions. His desire was, however, frustrated by the authoritative statement of the insuperable difficulties which would meet him in these districts, and hence his appeal to be sent to Bombay, where he would have the advantage of working in the hospitals, and not run the risk of being subjected to the opposition of an ignorant populace. It may yet happen that these lower animals do enjoy an immunity which will render their employment as a confirmatory test of the value of the discovery quite futile. Still hope must not be too soon abandoned, since it must be remembered that it was long after the discovery of the spirillum that relapsing fever was found to be communicable to monkeys by inoculation. Dr. Koch does not prejudge the question in his report; he does not claim to have discovered the "germ" of cholera; he only asserts that he has met with a peculiar organism, which may exist in such numbers because the conditions for its existence have been prepared for it by the disease, or which may, on the other hand, be the prime agent in the disturbance of function which constitutes the disease.

What is really important is that at length cholera, which has so long defied the researches of the pathogenist, is now being submitted to the same rigid and careful investigation that has been so fruitful in its application to other infectious diseases. It is quite true, as has been before remarked, that a new era in etiological inquiry has been opened; so that whereas upon this subject of cholera we have records as full and exhaustive as it is possible to have concerning its history and its geographical extension, and the progress of its epidemics, we may hope to see it investigated to the full from this new stand-point. It is easy to be too sanguine of the results of such an investigation. It may be doomed to failure, but the possible results are worth the labor that will be expended upon it. And we may be sure of this, that it could be committed to no better hands, for it will be dealt with by men who, by dint of skill and patience, have achieved great things in the field of pathology, and who will work with methods which have stood the test of experience. Until their research into cholera is crowned with success, it would be idle to speculate upon the light that may thus be thrown upon its prophylaxis and treatment.

DYSMENORRHOEA.

THERE are few subjects more worthy of sound study than dysmenorrhœa. It has received for the last fifty years more attention at the hands of gynecologists than ever before. But still it cannot be said that authorities are agreed on its essential causes. For a long time it came to be re-

garded as eminently a case for treatment by specialists. The mechanical theory of its causation largely ruled practice, in some few cases with brilliant relief, and perhaps cure, in others without success, and often with the effect of adding to the mischiefs which it was intended to remove. The very nature of the complaint, and the fact that in its serious forms it affects chiefly unmarried women, render the complete investigation of it a matter of much difficulty. The existence of more or less dysmenorrhœa in the majority of women is a fact. Even those who are unwilling to recognize in this fact any argument against the capacity of women for competing in the labor market with men do not deny that in a large proportion, nearly fifty cent., this dysmenorrhœa is considerable in amount. We have before us a paper by Dr. John Williams on the Natural History of Dysmenorrhœa, which was read last year before the Obstetrical Society of London. We can do little more than direct attention to Dr. Williams's principal conclusions from a large and painstaking observation of several hundred cases. He divides his cases into two sets—first, cases of primary dysmenorrhœa; secondly, cases of acquired. The acquired cases are so few (22) compared with the others (873) that we need not here allude to them. It is not easy to do justice to the details which constitute the interest of such a paper as the one under notice. But we can give his conclusions, and after doing so emphasize the chief of them. His conclusions are as follows:—

1. "Dysmenorrhœa should be studied first under the least complex conditions—in single women.
2. Dysmenorrhœa in single women is rarely acquired; it is almost invariably primary—viz., it appears with the menstrual function.
3. Dysmenorrhœa in a few, but rare, cases ceases spontaneously a few years after puberty.
4. Marriage, if sterile, aggravates the disorder in many cases; it is only very seldom that it relieves the pain.
5. Childbearing cures a large number of cases, and it is not impossible that were all puerperal complications excluded it would cure every case.
6. The proportion of sterile to fertile women subjects of primary dysmenorrhœa is one to twelve.
7. Menstruation begins in women who become sufferers from primary dysmenorrhœa at about the estimated average age for the appearance of the function in London.
8. Menstruation is regular in about two-thirds of the cases, and irregular in about one-third.
9. The menstrual fluid is profuse in about two-fifths of the cases, scanty in about one-half. It contains clots or shreds in about three-fourths.
10. The changes which take place in the fluid in the course of dysmenorrhœa are various, and cannot at present be classified.
11. The uterus is imperfectly developed. It may be too short, or too small in volume, or it may be defective in both respects. The cervix may be conical, and the os small and round, but stricture of the canal in any part of its course is infinitely rare.
12. The changes in the uterus due to dysmenorrhœa are slight hypertrophy, erosion and eversion of the mucous membrane of the cervix, and catarrh. The cavity increases but little in length, for after years of suffering it measures rarely more than two and a half inches in length. In the early stages the tissues of the uterus

are in some cases soft; in the more advanced, hard. 13. The hypertrophy of the uterus is probably the result of periodically increased muscular action. 14. Ovaritis and perimetritis are possible consequences of dysmenorrhœa. 15. The menstrual pain is the result of spasm of the uterus, excited by the separation and expulsion of shreds of decidua and clots, in an organ whose sensitiveness in the performance of its function is enhanced by inappreciable conditions of tissue dependent on imperfect development, often associated with others, such as anæmia."

Dr. Williams endorses the general opinion that the separation and expulsion of membrane in typical cases have a causal relation to the pain, chiefly by exciting spasm of the uterus, which in a few cases leads to its enlargement. Ovarian pain and inflammation are rare in his experience, and when they occur probably are consequences rather than causes, of dysmenorrhœa. Another very noticeable point in his conclusions is the infrequency of stricture of the cervix. The cervix may be conical and the os small and round, though in some cases the os is patulous, but stricture of the canal is infinitely rare.

The most striking facts in Dr. William's investigations have reference to the important evidence of imperfect development of the uterus. His conclusion is expressed in No. 11 of the above series. He examined physically 21 of 50 cases under twenty years of age. In 15 of these 21 cases the uterus was smaller than normal. Between twenty and twenty-five years there were 62 cases, of which 40 were examined. In 14 the uterus was of small size, in 1 very small; in 1 it was like a thick cord lying on the left side of the pelvis; in 3 it measured two inches only by the sound, but the body was no thicker than the cervix; in the remaining 8 it was estimated by bimanual examination to be smaller than normal; and similarly, though less, in the later quinquennial periods. In the later periods there is sometimes, as is said in the Conclusions, a partial hypertrophy of the organ, the canal still often being of short length.

This observation of the imperfect development of the uterus is consistent with the fact that dysmenorrhœa occurs more frequently in delicate and ill-exercised girls than in others. The whole drift of Dr. Williams's views is to pursue a constitutional and rational treatment of such cases rather than a mechanical one. But we content ourselves with directing this much attention to a very original and painstaking contribution towards the elucidation of a very difficult subject.

DR. CLIFFORD ALLBUTT'S ADDRESS ON MEDICAL ETHICS.

We revert with pleasure to the noble Address of Dr. Clifford Allbutt, in which he deals faithfully and candidly with the profession in regard to what he considers the faults and failings of its members. It is no slight advantage to be told our faults, not

by a candid friend, but by an actual brother, one who is sure to

"Be to [our] virtues very kind,
And to [our] faults a little blind."

There have been few more eloquent tributes to the good qualities of the medical practitioner than that of Dr. Allbutt's in this address. We are on this account only the more anxious to know what he can tell us of our defects and faults. We may differ from him or we may agree with him, but we cannot be indifferent to his judgment, when it is mingled with so much charity and so much praise. Let us face then, what Dr. Allbutt has to say of our shortcomings, always remembering his exquisite exception of Leeds, as a place where he could not have discovered the little faults which sometimes mar the beauty of medical character and the happiness of professional life. What are these faults? They are soon told, and resolve themselves into two or three.

"Our worst fault is that we are a somewhat touchy and jealous class," especially when compared with our cousins of the Bar. Medical men, excepting always "the harmonious brotherhood of Leeds," are too often jealous of each other and tenacious of their own claims. We too readily assume property in patients. We forget the right of the sick man to consult whom he pleases; and when he does so, we lack imagination enough to put ourselves in his place and make the necessary allowance. The same lack of imagination often prevents us from putting ourselves in the place of a brother practitioner who may have been called to one of our cases, and we give place to distrust and dislike. It would be easy simply to deny the accuracy of these suggestions or the faithfulness of the portraiture, or to dismiss the whole subject with the useless regret that we do not all live in Leeds, whose atmosphere must have in it something more exquisite than the smoke which is apt to absorb the attention of a casual straggler in Briggate. It is better to deal faithfully with so faithful a brother, and to say what we can in mitigation of his charges, and in support of his suggestions for diminishing the little friction that jars with the general harmony and good will of the profession. It is difficult to draw any close comparison between men so differently situated as the members of the Bar and the members of our profession in general practice. The situation is different, and the power to hurt a brother, as the temptation to do so, is different. Dr. Allbutt has in a significant sentence indicated the difference. The work of barristers is chiefly conducted with open mouth in open court. That of medical men is private, almost secret. And in the privacy of a bedchamber it is often more easy to kill a reputation than to save a patient. It may not be in any direct way or by any direct word, but by faint praise, or by a shrug of the shoulders or a shake of the head. We cannot surpass Dr. Allbutt's own words: "Unlike the Bar, we do not

play with our cards above the table. In our more intimate work, it is terribly easy for one doctor, *by little intangible tricks*, to elbow out or depreciate another." The intelligence of the friends of the sick is often so slight, their knowledge of disease necessarily so limited, and their judgment perhaps paralyzed by fear and misgiving, that any impression can be made on them by one doctor disposed to injure another. But as to the frequency of this kind of conduct? We are glad to tell Dr. Allbutt that is not much commoner out of Leeds than he finds it in that musical place. A few discordant notes give an exaggerated notion of the real harmony of the profession, and we venture to say that there are many villages with two doctors, and many towns with ten, who give very brotherly help to each other. If there is any less of brotherly and dignified feeling in the profession than there used to be, we should attribute it largely to the unfaithfulness of the examining and ruling bodies of the profession, who have admitted wholesale to the profession men who were not worthy of it, and have declined all ethical or judicial functions in regard to those they admit.

On one point Dr. Allbutt's remarks are worthy of the deepest consideration; medical men have no property in patients. The freedom of patients is often overlooked. It would be terrible indeed, with the limitations of personal wisdom and of medical art, if the friends of the sick had not the absolute right of choice from the whole medical profession. Some medical men shirk consultation; they claim a sort of right to be the exclusive advisers of their clients. Others will only enter into consultation with those whom they think fit to meet. The wish of the patient is little regarded by them. Such persons are apt to treat with scant cordiality a brother practitioner who, under any circumstances, sees a patient whom they had come to regard as their property. For the practitioner who, by unjust or unbrotherly disparagement, by dogmatism, or by any "little intangible tricks" of quackery or vanity, disturbs the confidence of a patient in his ordinary adviser, we have a feeling that we would rather not give a name to; but of the freedom of patients to consult any practitioner they please, and of the freedom of practitioners to see any patient that fairly wishes to consult them, there should be the amplest recognition. Patients who dodge from doctor to doctor have their own punishment, and they lose that inestimable advantage enjoyed by faithful patients—the personal and human interest of their medical adviser. We agree with Dr. Allbutt that there should be more consultation among medical men. It would often be a great kindness and comfort to patients. It would increase the mutual respect and trust of medical men and would attenuate and lighten the great responsibilities of their life.

One point more in Dr. Allbutt's address is good. "Offences must needs come," even between well

meaning and kindly practitioners. How can they be best removed? Dr. Allbutt says by personal interview: "Go and tell thy brother." The pen is never more apt to be a man's master than when he has a grievance, and ink is indelible. Our own experience as referees in many such cases tells us that a letter is often not avoidable; but it is a bad way of beginning to try to settle a quarrel. When we feel injured, the assumption should oftener be that we are misinformed. Such an assumption would often be justified, and when it is not it makes gentle words and a dignified statement easy, which will often convince an offending brother, which is as great triumph as to regain a lost patient.

CEREBRAL LOCALIZATION.

It is an interesting and noteworthy fact that pathological observation is doing more to advance our knowledge of cerebral functions than physiological experiment. At any rate this would seem to be true of the doctrine of cerebral localization, for whereas physiologists agree to differ upon the interpretation of their experimental results in this matter, the clinical and pathological evidence in support of the doctrine is rapidly accumulating. Dr. Sharkey's recent paper read before the Royal Medical and Chirurgical Society is an instance of this, for, although clinical details were wanting, the lesions found in the brain and so accurately sketched by him harmonized very well with the doctrines of Ferrier. In the current number of the *Revue de Médecine* MM. Charcot and Pitres commence a series of articles upon the subject supplementary to a like contribution to the same periodical made by them four years ago, when they collected and sifted all the recorded cases of cortical lesions bearing on the question of the localization of motor function. They point out that since that time many observers have become convinced of the truth of the doctrine, which has been upheld particularly in the writings of Ferrier, Boyer, Nothnagel, Exner, and Wernicke; but they confess that there is not yet general conviction. Some of the opponents of the theory base their objections on abstract philosophical notions, or on doctrinal subtleties which MM. Charcot and Pitres decline to discuss. Others rely too exclusively upon the results of experimentation in the lower animals—results often contradictory, and always more or less complicated. The writers, whilst recognizing the value of physiological experiment, deprecate the propriety of basing upon it too rigid deductions of human cerebral function. In the hope of convincing the still large number, who only half accepted the truth of the doctrine, they have collected upwards of 200 cases of cortical lesions recorded in the past four years, not omitting those cases which seem to tell against the theory. The first section of their work is published in the current number of the *Revue*; it deals with cases of destructive lesion of

the cortex situated outside of the motor area, and, unaccompanied by motor disorder. Thirteen cases of lesion of the prefrontal region are given, in which it is also proved that the root of the frontal gyri may be diseased without causing motor paralysis. Then follow three cases of lesion of the occipital lobe, fourteen of the temporo-sphenoidal, and three of the parietal lobes. They do not think that facts justify the opinion held by some that the inferior parietal lobule is concerned with the movements of the eyes. Only one case of lesion of the insula is given; but as in no case has it happened to be the only part involved, it is not possible to infer much from it. Then follow ten cases of multiple cortical lesions, seated in the "non-motor" areas, making a total of forty-four cases, which go to prove, as the writers think, that there exists a large portion of the surface of the brain the destruction of which is not followed by any permanent disorder of voluntary motion—the convolutions which, in man at least, subserve motor functions being the frontal the ascending parietal, and the paracentral lobule. Unless these regions be involved by a cortex lesion, directly or indirectly by compression or irritation, motor disturbances do not arise. Moreover, they believe that these motor areas are symmetrical in their distribution in the two hemispheres. The second portion of their essay will contain records of cases of destructive lesion of the cortex in the motor zone, with paralysis; a third section will deal with the relations of partial epilepsy to irritative lesions of the cortex; and in the final section they propose to study the cases which present features that do not support the deductions drawn from the majority of cases.

CATHETER FEVER.

SIR ANDREW CLARK, in a short address to the members of the Clinical Society on their reassembling after the vacation, drew attention to the grave and usually fatal constitutional disturbance which not rarely follows the passage of a catheter. He believes that this danger is not sufficiently appreciated, and that surgeons do not fully understand the cause of the malady. At the same time, his remarks took rather the form of an appeal for information on the exact cause and nature of this "catheter fever." Sir Andrew was careful to point out that he was not referring to the chills which often follow the passage of a catheter—the so-called urethral fever—but to a more serious malady, attended with pyrexia, rapid weak pulse, dry tongue, anorexia, and adynamia, which generally ends fatally in a few days. The first thing that suggests itself in considering these cases is the fact that they are not met with as a sequel to catheterism in men who have been previously free from disease of the urinary organs. The history always is that there has been long-standing stric-

ture, or enlargement of the prostate, with atony of the bladder and chronic retention of urine, or calculus in the bladder; and that then, on some slight irritation of the urethra or bladder, such as is caused by the passage of a catheter, this serious chain of symptoms ensues. This undoubtedly throws great light on the pathology of the cases. The condition which is common to these various evils is a chronic interstitial inflammation of the kidney, especially of the cortex. The kidneys thus diseased may be little altered in their general appearance, but the capsule is a little less readily stripped off than usual, and leaves the surface of the organ irregular, and the cortex itself is abnormally pale. With the microscope, however, the change is at once to be detected in a cellular and fibrous intertubular infiltration and a granular condition of the epithelium. There may or there may not be superadded to this absorption of the pyramids the result of the pressure of urine dammed back in the pelvis of the kidney. When the cortex of the kidney is in this condition, a slight irritant is sometimes sufficient to light up an acute and fatal inflammation. This irritant may act directly upon the organ, as when the urine in the pelvis undergoes putrefaction; or indirectly in a reflex manner, as in the passage of a catheter or other instrument along the urethra, or in the performance of any operation upon the urinary tract. This acute interstitial nephritis tends to run on to suppuration, and causes lines and spots of pus or larger abscesses to be scattered through the cortex; the organ is at the same time swollen and greatly congested. The symptoms to which this acute affection gives rise are fever, usually attended with one or more rigors, nausea, often vomiting, dry brown tongue, loss of appetite, drowsiness, absence of spontaneous pain, though in some cases there is tenderness in one or other loin, failure in the pulse and then, later on, cold clammy skin, deepening stupor, perhaps diarrhoea, coma, and death. Convulsions are very rare; oedema is absent; and as the urine is secreted in moderate quantity up to the end of life, the symptoms do not present a likeness to those familiar to physicians in Bright's disease. In the chronic form of the disease the urine is secreted in considerable quantity, is of low specific gravity, and only rarely contains a very small trace of albumen, and an occasional hyaline cast may be detected in it. In the acute form the urine is generally less abundant and more albuminous. But as there is often an added catarrh of the bladder, it is impossible to determine accurately the state of the urine as secreted by the kidneys. We would suggest, then, that the cases referred to by the President of the Clinical Society are those of chronic interstitial nephritis set up by chronic disease of the bladder, prostate, or urethra, in which an acute renal inflammation is induced by the passage of a catheter. The subject is a very important one, and now that attention has been

called to it in so prominent a way, it is probable that the true nature of these cases will be more generally recognized.

MR. HUTCHINSON'S ADDRESS.

MR. HUTCHINSON suggested a new departure in the method of diffusing knowledge in his address read at the first meeting of the Ophthalmological Society this session. He proposed that memoranda dealing with the treatment of many common affections of the eye should be prepared and issued to the members of the medical profession under the guidance of the Ophthalmological Society. In order clearly to understand the nature of the proposal, it is necessary, and will conduce to perspicuity, to discuss, first, the reasons for the issue of such memoranda; secondly, the method by which these documents should be distributed; and, lastly, why this kind of thing should be carried out rather by a corporate body than by other means. The subject, it will thus be seen, has to be treated from the points of view of theory, practice, and ethics.

There can be no doubt that a large number of cases of corneal ulcer do continually get worse mainly from the want of knowledge of the existence of simple remedies, and more especially of that valuable preparation the dilute yellow oxide ointment of mercury. Again, as Mr. Hutchinson urged, the number of instances of loss of sight from acute glaucoma which occur every year even now must be considerable, and this may be chiefly attributed to the lack of information regarding the proper time for the employment of iridectomy. Many excellent general practitioners do not realize the fact that, notwithstanding the presence of acute inflammation, the immediate performance of iridectomy is precisely the remedy, not only because the tension of the globe is thereby relieved, but also because the inflammatory state associated with the glaucoma must disappear by the same act. When we consider that it is hardly possible for the busy practitioner to have much time to devote to the acquisition of special knowledge of ocular diseases, and when we reflect on the amount of mischief and loss to the nation which annually accrues from such, in a measure excusable lack of knowledge, we think enough has been put forward to show that the theory of Mr. Hutchinson's new departure rests on a sure basis. From the standpoint of ethics there can be nothing savoring of quackery in the carrying out of the scheme under the auspices of the Society. All individual names would be suppressed in the idea of the issue of instructions under the abstract title of Therapeutic Memoranda of the Ophthalmological Society, so that no accusation could be made against the proposal on this score. There is yet the further argument, also alluded to by Mr. Hutchinson, that advertising quacks may establish a lucrative business out of the knowledge of one or two simple

remedies, which, however powerful in doing good, are also probably for the most part powerless to do evil. Altogether, we think the suggestion of Mr. Jonathan Hutchinson is of considerable importance, and hope that the Society mentioned, and possibly other more or less special societies, may see their way to the adoption of his overtures.

Reviews and Notices of Books.

The Extra Pharmacopœia of Unofficial Drugs and Chemical and Pharmaceutical Preparations. By WILLIAM MARTINDALE, F.C.S., late Examiner of the Pharmaceutical Society, and late Teacher of Pharmacy and Demonstrator of Materia Medica at University College. With References to their Use, abstracted from the Medical Journals, by W. Wynn Westcott, M.B., Deputy Coroner for Central Middlesex. London: H. K. Lewis. 1883.

Sixteen years have elapsed since the publication of the last British Pharmacopœia, and it has long since ceased to occupy the high position it once held as a work of authority. New drugs and new preparations have come into general use, and the whole aspect of therapeutical science has undergone a gradual but sweeping change. Operative surgery has been greatly influenced by the introduction of new antiseptics and new anæsthetics, dermatology by the invention of petroleum ointments, and pharmacology by the discovery of such important medicinal agents as salicin and salicylic acid, chloral and croton chloral, chrysophanic acid and eserine, gelseminum and gelsemine, homatropine and hyoscyamine, jaborandi and pilocarpine, and nitrite of amyl and nitro-glycerine. In the introduction of these and other new remedies the author of the work before us has, during the last ten or fifteen years, played a by no means unimportant part. He has extracted the active principles from many of our most valued drugs, and has reduced them to a form in which their properties can be investigated by the pharmacologist and their uses studied by the scientific therapist. It is therefore with much pleasure that we record the appearance of an "Extra Pharmacopœia" designed to supply in some measure the deficiencies of that work which is conventionally supposed to represent the present condition of pharmacy in this country. That any one writer could ever hope to provide for all the shortcomings, or even to correct all the inaccuracies, of the official publication is not for one moment to be supposed; but Mr. Martindale has given us a very useful instalment, and his example will, we have no doubt, be quickly followed by others who, like himself, are dissatisfied with the present antiquated condition of affairs. The drugs mentioned by him in the new Pharmacopœia are viewed not only from a pharmaceutical, but also to some extent from a medical, aspect, references to their properties and uses being freely given. The area of selection, we are told, has been limited by personal experience, official drugs being introduced only when non-official preparations are in use. The chemical nomenclature has been adopted throughout, except where official chemicals are referred to, and then the Pharmacopœial name has been provisionally retained. The author expresses his regret that the metric system has not as yet been definitely introduced into this country, and

that for practical reasons he has been compelled to retain for the present the old-fashioned weights and measures. On the Continent the new system is almost universally adopted both for dispensing and preparing medicines. In Germany, for example, the quantities of the ingredients are given in decimals; the gramme, which is taken as the unit, being, as a rule, not specifically named.

The first article is on jequirity, the new remedy for granular lids; and this is followed by an excellent description of the preparations of borax and boracic acid. Under the head of carbolic acid, a good account, compiled from various sources, is given of the antiseptic treatment, and no less than twenty-three preparations of carbolic acid are mentioned, most of them of undoubted value. The "carbolyzed smelling salts," which will be found useful in the treatment of hay fever, coryza, and allied affections, are evidently founded on a well-known proprietary article. The account of goa powder and chrysophanic acid is thoroughly practical, and will be read with interest. Numerous references are given to the action and uses of salicin and salicylic acid, a long extract being made from Ringer's Therapeutics. Aconitia is described as an alkaloid obtained from *Aconitum napellus*, and "probably other species of aconite," but no authority is given for the last assertion, although it is stated that English aconitine (Morsen's) is, according to Flückiger, supposed to be identical with the pseud-aconitine obtained from *Aconitum ferox*, the Bish poison. We feel constrained to take exception to the introduction of the "special preparation" called "oleo-anodyne," which is said to be a combination of "aconitia, atropia, morphia, and veratria, with oleic acid." We have no doubt that, as a local application, it may afford relief in some forms of neuralgia, but the mixture of a number of active principles thrown promiscuously together, is not to be encouraged, and is out of place in a work possessing any claims to scientific accuracy. The *Argaracus albus*, or white agaric, is recommended in doses of from ten to fifteen grains as a remedy for the night sweating of phthisis. Care must be taken not to confound it with the fly agaric, *Amanita muscaria*, which is used for the same purpose, but is a much more active drug. The hypodermic injection of hydrochlorate of apomorphia is mentioned as an emetic, but the statement that the aqueous solution is "not very stable," is vague and might prove misleading. The account of the origin and source of atropia is correct, and shows an intimate acquaintance with the recent literature of the subject. The uses of the various salts of homatropia are referred to, and we are very properly warned that "they are costly." Directions are given for making the sulphide of calcium pills now so frequently prescribed for boils, carbuncles, and enlarged scrofulous glands. Permanganate of potash pills are directed to be made with kaolin ointment, a mixture of equal parts of vaseline, paraffin, and prepared kaolin. The author brings a serious charge against the official camphor-water, which is said to be of uncertain strength, the water taking up a variable quantity of camphor, according to the temperature at which it is kept. "A definite quantity of camphor dissolved in a small but certain quantity of spirit, and this added to a measured quantity of water, would make a more uniform preparation." Under the title of "spiritus camphoræ fortior," a formula is given for the essence of camphor now so largely used in the treatment of summer diarrhoea. Tannate of cannabin is a salt likely to prove useful, although its properties have as yet been but little investigated. The tests for chloroform are given concisely and clearly, but the information con-

cerning another anæsthetic, bichloride of methylene, is meagre in the extreme, consisting of only a short quotation from Garrod. The composition of the substance—we might even say its very existence—has been so freely discussed of late that we had hoped for some definite statement on the subject. The liquor chloromorpha, or chloromorpha solution, the formula for which is given, is evidently intended as a substitute for the too popular chlorodyne. The account of the cinchona barks and alkaloids is excellent, and is by far the best we have seen. *Convallaria majalis* is briefly mentioned, and, in addition to convallarin and convallamarin, an extract is recommended. The author appears to entertain some doubts, perhaps justly, as to the value of damiana as an aphrodisiac, for he passes it by with the shortest possible notice. The emblio-myrrabolin fruit is spoken of as a good laxative, and we can endorse the statements made as to its efficacy. Directions are given for the use of defibrinated desiccated blood, a remedy of much value as an enema in cases of gastric ulcer. A great deal of useful and practical information is given in the article on the oleates, but the preparations commonly called Shoemaker's oleates should have received more attention. The salt here called "pulvis zinci oleates" is very useful, and is a great advance on the compound originally sold as oleate of zinc.

The purely pharmaceutical articles are, as might be expected from an old and experienced teacher of pharmacy, thoroughly practical. The section on pills shows that the author has not failed to appreciate the requirements of prescribers. The modern method of varnishing pills is a great improvement on the old-fashioned custom of covering them with dirty flour. It is to be regretted that the American elixirs are so little used in this country as flavoring agents. A drachm of "simple elixir," a formula for which is given, added to an ounce of almost any liquid medicine will make it palatable. The preparations of the prunus virginiana, the wild cherry bark of the United States Pharmacopœia, might also be used with advantage for flavoring purposes, especially as an addition to cough medicines. We have mentioned only very briefly some of the more important articles in this interesting work, but every page is replete with valuable practical information, which will be found of the greatest use not only to the pharmacist, but also to prescribers.

Though we have only dealt with the pharmacological portion of this work, it would be ungracious not to notice Dr. Westcott's carefully prepared references to the various drugs.

Practical Treatise on the Diseases of the Uterus. By A. COURT. Translated by AGNES McLAREN, M.D. London: J. & A. Churchill.

THIS is by the distinguished Professor of Clinical Surgery at Montpellier. It has been translated by his pupil and some time private assistant, Miss McLaren. The translator was thus placed in very favorable circumstances for producing the views of her master in an English form, and she has done her work well. Court's work has been well known for years to gynecologists in France and elsewhere, and it has been held in high esteem, especially in France, as one of the ablest expositions of the views of the French school. Like the majority of works, both great and small, on the subject of which it treats, the book is defaced by the teachings of what are called the "more advanced" gynecologists of the day, by which are usually meant those who accept what may be called the uterine reflex theory of pains and sufferings, grafted on the mechanical theory

of uterine pathology in its most extreme form, and who carry out these views of uterine disease in practice to their logical ending—that is, perpetual local interference.

The work is divided into an introduction and two parts. The introduction treats of the anatomy, physiology, and teratology of the organs of generation, and of this part it is sufficient to state that it contains a fairly full account of the subjects. Part I. is called a General Survey of Uterine Disease, while Part II. treats of uterine disease in detail, so that the work presents a totally different arrangement of matter from that usually met with in works on diseases of women. Such an arrangement presents many advantages, for it gives an opportunity in the first part to discuss the principles which underlie and run through the second. The first part of the book contains its pith and marrow; the second part is the first carried out in detail. The general survey treats of the diagnosis, symptomatology, treatment, and general characteristics of uterine disease. The uterus has for a long time been regarded as a sort of boggy which casts its evil shadow over any or all parts of the body; there is apparently no condition of it from the blighting influence of which the other parts of the body do not suffer; its power for evil appears to be simply marvellous, to exceed that of any other and all other organs in the body put together. This mighty power for mischief possessed by the uterus Professor Courty accepts with implicit faith, but on what evidence we have not discovered. On page 97 we read, "How often is one consulted for neuralgia or hysteria; for symptoms manifested in the stomach, the heart, or the liver; for digestive troubles—anorexia, nausea, diarrhoea; and for all the train of evils depending on poverty of blood—anæmia, chlorosis, emaciation, and exhaustion; but the natural and symptomatic manifestations of an unrecognized uterine malady!" We cannot help expressing a devout wish that in most of the conditions named the uterine malady may remain unrecognized, for then there may be some chance of relief and cure to the patient, for we find, "that very often an apparently insignificant disorder of this organ [the uterus] is felt throughout the body to a quite disproportionate extent." Tracing reflex symptoms to their source is a work of extreme difficulty, and although it is well established that pregnancy gives rise in many cases to a variety of distant phenomena, yet this is a very different thing from uterine reflex, and it may be safely affirmed that the evidence in favor of the statements we have just quoted is of the flimsiest character. A little further on we meet with the following: "It is of importance to proceed step by step, and to pass from general to local symptoms. . . . It is essential that the patient should be led steadily to the conviction at which the physician has arrived, for this conviction is the only means by which he can hope to make her understand the necessity for a local examination, and agree to submit to this painful trial. . . . Women are so much afraid of polypi, cancers, and ulcerations. . . . that the reasonable terror inspired by these affections will not only remove their repugnance to an examination, but will make them earnestly desire it." The wretched patient, who suffers from some insignificant and unimportant affection of the uterus, or perhaps no affection of it at all, is put through this horrible mental agony, and then is told she has an ulcerated or a displaced womb, and she becomes in a great many instances an invalid for life, for she gets displacement or ulceration of the brain, and it would be as easy to remove Helvellyn and plant it in Wicklow as to remove the impression produced on her mind.

The symptoms of these diseases are almost countless, and we find also that the medicaments and means of relief are extremely numerous. The late Dr. Churchill, having given not an exhaustive list of the many drugs which were said to have benefited amenorrhœa, concluded that the disorder must be very difficult to cure, and we believe that it would be much better for women to put up with many of the minor ills from which they suffer than to undergo the treatment recommended for them in the work before us. Take, for instance, amenorrhœa. According to Professor Courty, idiopathic amenorrhœa gives rise to very distressing symptoms, such as nervous disturbances, chloro-anæmia, headache, and drowsiness. It is true that these conditions are frequently met with in the same person, but there is no evidence to show that the general symptoms are caused by the amenorrhœa. There is evidence to the contrary, however. There are many women living in whom the uterus has been amputated during menstrual life, and amenorrhœa has been established, and these women have not suffered in consequence. McClintock pointed this out years ago, and yet, among others, means which have proved fatal in many cases are recommended for the treatment of amenorrhœa in the work before us. Again, if we take versions and flexions, we find among the many symptoms said to be caused by them, constipation, frequent micturition, and retention of urine; and these are said to be due to the pressure exercised by the displaced womb. We do not know what the weight of the uterus may be when suspended in the broad ligaments, but out of the body, as a dead weight, it is about an ounce and a half, it is evidently much less when suspended in the pelvis; at most, however, it cannot be heavier than a coil of small intestine two inches in length filled with feces, and the weight of the latter has never been suggested as a cause of constipation or of retention; and it is difficult to imagine how a bent or an inclined uterus, so long as it is freely movable, can give rise to any such troubles. Courty adopts the mechanical theory of the uterine pathology in its fullest extent, as well as the now exploded doctrine of ulceration, and his treatment is adapted to these views.

We have said enough to give an idea of the book. There is, however, one other matter which we must mention. Dr. Matthews Duncan has written a preface to the English translation. Should anyone, however, buy the book with the idea that this preface contains a recommendation of it he will be disappointed. The preface appears to have been written because "I have had the privilege of her [Miss McLaren's] friendship since her childhood, and know her excellent qualities." We cannot help regretting that Dr. Duncan consented to do this, for many will naturally think that in doing so he countenanced or recommended a work which promulgates doctrines of which he has been throughout his life one of the foremost opponents.

A History of Tuberculosis from the time of Sylvius to the present day. Being in part a Translation, with Notes and Additions, from the German of Dr. ARNOLD SPINA. Containing also an account of the Researches and Discoveries of Dr. Robert Koch and other investigators. By ERIC E. SÄTTLER, M.D. Cincinnati: Robert Clarke & Co. 1883.—The lengthy title of this book sufficiently indicates its nature. It will be remembered that in the spring of the present year Dr. Spina, the assistant to Professor Stricker, of Vienna, published a monograph upon Tuberculosis, in which, after

entering at length into the history of the subject, he described certain experiments and observations of his own tending to disprove the accuracy of Professor Koch's inference as to the etiological relation between the bacillus and tuberculosis. A controversy sprang up between Vienna and Berlin, and Professor Koch himself replied to the onslaught in a manner which showed that, admirable observer as he is, he was not fitted for controversy. Convinced of the truth of his own observations, he dealt less temperately than might have been expected of a man of science with the views of Dr. Spina and others who had ventured to doubt his conclusions. Dr. Sattler's closing words in this volume place the matter in its correct light. He says: "We are yet on the threshold of a great discovery, and it will require constant inquiry, patient investigation, and deep research before the true relation of bacilli to tubercle, and the part they play in their pathology and causation, are fully determined." The book consists of seven chapters, the first five of which are a translation of Dr. Spina's historical survey, which commences with the pathological anatomy and histology of tuberculosis, and then deals in turn with the various experimental researches by inoculation, inhalation, feeding, and by the inoculation with "pure tubercle virus." The remaining chapters are devoted by Dr. Sattler to an account of Professor Koch's experiments, and to the very numerous investigations that have taken place in all parts of the world since the discovery of the bacillus, including Dr. Spina's researches. As the work is thus so largely based on the latter's "Studien," it is not surprising that the editor should have himself adopted a rather sceptical attitude with regard to the position claimed by Professor Koch. At the same time, Dr. Sattler is careful to be as impartial as possible, as may be gathered from the sentence above quoted. He has done good service in bringing this work before English readers; and when Dr. Koch's work upon Tuberculosis (which he completed, we believe, before his departure for Egypt) appears, we trust it will find as prompt and careful a translator as has fallen to Dr. Spina's lot.

General Medical Chemistry.—By R. H. WITTHAUS, M.D., Professor of Chemistry, University of Vermont. London: Sampson Low & Rivington. 1882.—We have to apologize for the delay that has occurred in noticing this work; it, however, reached us somewhat late, and at a time when there was considerable pressure on the space at our command. The delay, however, has given us a better opportunity of making ourselves acquainted with it, and a minute perusal has convinced us of its high degree of excellence and thorough trustworthiness. It is a book that is much wanted, though probably it will be found more useful as a work of reference than as a text-book, and even then be of more value to the medical officer of health, the food analyst, the toxicologist, and pharmaceutical chemist than to the clinical physician and physiologist. Indeed, the parts referring to physiological and pathological chemistry are the weak points of the work; not that the statements are unreliable, but simply because much useful information has been omitted, and the material used too much condensed. In a second edition this should be rectified, and if the size of the volume must still be limited, the space required might be advantageously gained by cutting down much of the purely theoretical part of the work, dealing with the classification of the elements and carbon compounds. We have many excellent treatises dealing with this part of chemistry, but very few, and those confined to individual particulars, relating to its practical applica-

tion to matters purely medical. If Dr. Witthaus therefore would consent to part with that portion of his work relating to general chemistry, or put it in a separate volume, and develop the more purely medical and technical part of the work he would supply a want at present much felt. That he is well fitted for the task is shown by the admirable chapter he gives to the consideration of "water" in all its chemical aspects. With regard to the chemical portion of the work, we cannot speak in too high terms of its thoroughness and completeness; for example, among the numerous reactions given for glucose, he describes the indigo carmine test, long overlooked and forgotten, thus anticipating Dr. Oliver in the revival of this elegant and useful urinary reagent for clinical purposes.

Rheumatism, Gout, and some Allied Disorders By MORRIS LONGSTRETH, M.D., Physician, Pennsylvania Hospital. London: Sampson Low & Rivington. 1883.—The title of this work is misleading. It contains nineteen chapters, eighteen being devoted to the consideration of rheumatism and only one to gout. The work, too, seems a little behind the time. No notice is taken of the statistics with regard to results obtained by the salicylate treatment, contributed by the leading physicians of the metropolitan hospitals during the debate at the Clinical Society, 1881. We have looked in vain for any reference to the subcutaneous nodules, so well described by Barlow and Warner, as being associated with the rheumatic diathesis. The consideration of the relationship supposed to exist between chorea and rheumatism is dismissed in the following sentence: "Some of the other forms of manifestation of rheumatism of a nervous character are chorea, hysteria, contraction of the extremities, tetanus, insanity, etc." The best chapter in the book is that devoted to a consideration of the various theories that have been started to account for the nature of the disease. The style is good and the arrangement clear, but a good deal more work must be expended on it to make it rank as a first-rate treatise on the subject.

Pathology and Treatment of Nerve Weakness. By C. L. DANA, M.D. New York: Trow's Co. 1883.—There is much more of treatment than of pathology in this little lecture, which was read at a meeting of the Practitioners' Society of New York in May, 1883. A view of the pathology of neurasthenia is propounded which is in accord with the teachings of a yet unformed molecular physiology. The number of means here given for disestablishing the neurasthenic state of molecular instability is certainly large enough: General principles; hygienic; internal medication in the way of sedatives, tonics, stimulants; surgical measures; electricity; hydrotherapy; revulsives and inhibitors; dry cups; massage (Weir-Mitchell treatment); special diet; and mental therapeutics.

Cholera a Disease of the Nervous System. By JOHN CHAPMAN, M.D. London: J. & A. Churchill. 1883.—This brochure is a sort of *réchauffé* of Dr. Chapman's work on Diarrhoea and Cholera, published in a second edition in 1866. It contains a letter in English addressed to the editor of the *Journal de Médecine de Paris* by the author, a French version of which was published by that journal in August last. The second part of the pamphlet gives in full the review of the work on Diarrhoea and Cholera, the writer of which appears to have been Sir Andrew Clark, Bart. It is sufficient for us to say that Dr. Chapman believes that all the phenomena of cholera are due to hyperæmia of the spinal cord and sympathetic nervous systems, and that the most efficacious remedy for the symptoms of the algide stage of cholera is the spinal ice-bag.

The American Journal of Neurology and Psychiatry. August, 1883. New York: B. Westerman & Co.—This well-printed quarterly journal deserves to meet with success. The third number now before us contains a variety of material, some being of considerable interest and value. Of this description we may mention Dr. Hoffmann's article on *Researches in the Normal and Pathological Anatomy of the Grey Substance of the Brain*, with remarks on *Methods of Examination*; A Provisional Communication regarding a case of *Pons Hæmorrhage*, with *Descending Degeneration of the Stratum Intermedium*, by Spitzka, one of the editors. The other original articles are:—*Variola and Insanity*, by Dr. Kiernan; *On the Alleged Relation between the Speech Disturbance and the Tendon Reflex in Paretic Dementia*, by Spitzka; *Simulation of Insanity by a Criminal Lunatic*, by Bluthardt; *The Somatic Etiology of Crime*, by Henry Howard; *Alcoholic Insanity*, by Lewis Mason; *Report on the Recent Appearances observed Post mortem in a Case of Delirium Grave*, by Clevenger; *On the Brain of a Cat lacking the Callosum*, by Burt Wilder; *The Case of Diedrich Mahnken*, by Landon Gray; *A Case of Verbal Blindness with Right Lateral Hemianopsia*, by McBride; and on an *Authentic Case of Disappearance of the Tendon Reflex without ascertainable Pathological Basis*, by Spitzka. This last article relates the case of a doctor who had been in the habit of producing the knee-jerk on himself from his youth upwards. During the last seven years the knee phenomenon could not be got on either side. We should be cautious in drawing any rigid inference from such facts. The disappearance may be due to local conditions, or is it too much to suppose that some other phenomena more explicit in their significance may yet appear in the course of time? The journal further contains a most refreshing review of *Types of Insanity*, by Allan McLane Hamilton.

Medical Annotations.

"Ne quid nimis."

HONOR TO WHOM HONOR IS DUE.

We have received an extract from the ninth volume of the *Electrician*, which seems to show that the honor of having invented the electric telegraph really belongs to Edward Davy, a member of the medical profession, who, at the advanced age of seventy-seven, is now living in one of the Australian colonies. Davy's original paper appeared in the *Mechanics' Magazine* for 1838. An original manuscript, dated 1836, entitled "Outline of a new plan of Telegraphic Communication, by which intelligence may be conveyed with precision to unlimited distances in an instant of time, independent of fog or darkness," has lately been discovered among Davy's papers by his nephew, Dr. Henry Davy, of Exeter; and this, as well as others, have been placed in the hands of Mr. J. J. Fahie, who is the author of the paper in the *Electrician*. The first idea was to use static electricity for transmitting the signals; but this was soon abandoned, and the electro-magnetic properties of the voltaic current was the form of electricity upon which Davy ultimately relied, and the signals were made by the deflections of the needle of a galvanometer. His proposal was to use as many wires as there were letters in the alphabet, but these he subsequently reduced to half the number by making a deflection to the right convey one signal and

to the left another. When Cooke and Wheatstone applied for their first patent in 1837, Davy entered an opposition, lodging with the Solicitor-General of the time a full description of his own apparatus; and in November and December of the same year a working model of Davy's apparatus was shown in a room adjoining Exeter Hall. An examination of Mr. Fahie's paper leaves no doubt on the mind that Davy had a very clear notion of the electric telegraph, but it would occupy too much of our space to go into the technicalities and details. It seems that Edward Davy was born in 1806, studied at St. Bartholomew's, and became M.R.C.S. and M.S.A. in 1828. He soon gave up medical practice, and became a practical chemist, having a place of business in the Strand; and his ingenuity is evidenced by a "blow-pipe," a "mercurial trough," and a "diamond cement," which bears his name. It is probable that he would have succeeded with his invention just as Cooke and Wheatstone did, had he not lacked three necessary things: (1) backers with money, who believed in him and his inventions; (2) good men of business to advise him; and (3) "push," without which inventive genius is of no avail. Just as he had perfected his ideas, he left England and became one of the assayers to the Melbourne Mint. Had he remained at home to enforce his ideas with the necessary pestilent importunity, he might have reaped the reward of his genius. Davy had genius, but lacked another quality, needful but less lovely, and thus the story of his invention is the story, as Mr. Fahie says, of a "magnificent failure."

KAIRIN, THE NEW ANTIPYRETIC.

SINCE Dr. Filehne, a few months ago, introduced to notice the remarkable antipyretic action of kairin—an artificial alkaloid described as being the hydrochlorate of oxy-chinolin-ethyl—the drug has been given by others whose experience confirms that of the introducer. Thus Dr. Sas-setzki (*St. Petersburger Med. Wochenschrift*, Sept. 1st) states as his experience of its use in a case of typhus that kairin is a valuable antipyretic, doses of half a gramme reducing high fever to a normal temperature, which can be kept down by repeating the doses. The pulse falls together with the temperature, and the excretion of nitrogenous and phosphatic substances is lessened. The urine assumes a green color, which disappears very rapidly on ceasing the administration. It is curious that the fall of temperature in this case was not accompanied by sweating. No ill effects resulted from the drug. Another case is recorded by Dr. Knipping of Neuwied (*Berliner Klinische Wochenschrift*, Sept. 10th), which may be briefly given here. A young woman, about twenty years of age, suffered from puerperal pyrexia for about nine days. On the fourteenth day after her confinement she was allowed to rise and take a bath. Next day she complained of pain in the left thigh, and symptoms of parametritis appeared, which was not controlled by the application of ice, leeching, etc., periphlebitis of the left leg also occurred with much irregular pyrexia, and the temperature reached nearly 105° F. On the twenty-fourth day there occurred periphlebitis of the right leg, and the case was further complicated by intestinal catarrh, bronchitis, and some dulness at the apex of the right lung. The morning temperature was 104°; evening, 105.4°, with very slight remissions; pulse 120 to 130, small and irregular. Quinine had been given in full doses without any influence, and the weakness of the patient precluded a resort to cold baths, so that on the thirty-fourth day, when the temperature

reached 106.4°, and the heart was failing markedly, resort was had to kairin. It was given in doses of 0.5 gramme, in gelatine capsules, every hour. After the first dose the temperature fell to 102.2°, with profuse sweating; after the fifth, to 100.2°. The pulse did not correspondingly fall at first, remaining at 100. A reduction of the dose to 0.25 gramme was followed by a rise in the temperature to 105.4°, with return of the bad symptoms, so that 0.5 gramme was again given hourly for four hours, when the temperature had fallen to 101.2°. For the next four hours 0.25 gramme was given, with relapse of fever to 102.2° and 103°, again reduced to 100° by resort to the larger dose. The administration was continued for a week, and by the forty-first day the condition was much improved—temperature about 100.4°; and the intestinal and pulmonary symptoms had passed away. On now omitting the drug there was a slight rise in temperature, but this was easily controlled, and the case did well. In the seven days she had taken 220 doses of kairin without any toxic effects, beyond slight pricking sensations on the nose and forehead after the first dose. The urine became of a deep dark-green color, free from albumen and casts, the normal color returning if the drug was discontinued for twelve hours. The writer describes the sweating as being most marked, subsiding as soon as the kairin ceased to act and the temperature rose. He believes the drug in this case to have been the means of saving the patient's life, and insists upon the dose being repeated hourly if the antipyretic action is to be maintained.

COPPER AND CHOLERA.

The precise set of conditions necessary for the life and welfare of micro-organisms seems to be capable of very fine adjustment. Under some circumstances the development of bacteria may, so to speak, just go on, but with the introduction of another apparently trivial factor this development may become luxuriant. Or that plenteous growth may be determined by the removal of some injurious circumstance, seemingly of no great moment. It is exceedingly probable that the protoplasm of human organisms is just as sensitive to apparently small influences, though the effects may possibly be less obvious. In a paper by M. Bochefontaine, recently presented to the Académie de Médecine, treating of experiments on the antiseptic action of copper, the conclusion is arrived at that whatever action sulphate of copper may have on the contagious element of cholera, it has none on "*vibrioniens ou germes microbiques*." M. Béchamp said that from numerous experiments made in 1867 he had shown that the salts of copper and iron were able to retard the evolution of bacteria in certain cases; but that under other conditions, especially of the atmosphere, this evolution was not prevented. The statements which M. Béchamp has made are quite intelligible, but as much cannot be said of the conclusions of M. Bochefontaine, as reported in *L'Union Médicale*. It is high time that our terminology in regard to micro-organisms were settled. The statement that sulphate of copper has no action on "*vibrioniens ou germes microbiques*," is certainly capable of a variety of interpretations.

ELEPHANTIASIS ARABUM.

M. CORNIL has recently had the opportunity of examining the tissues and organs of a case of elephantiasis Arabum, complicated with albuminuria. The spleen was enlarged and advanced in amyloid degeneration; the kidneys also pre-

sented amyloid and fatty changes, whilst the liver was simply fatty. The skin of the affected limbs is described as being irregularly mammillated, warty, and ulcerated. The epidermis was greatly thickened, particularly the granular and horny layers. The papillæ were enlarged in all directions, composed of a loose connective tissue, containing flat and round cells; the capillaries were dilated, thin-walled, and full of blood. The dermis was enormously thickened, and its dense tissue appeared as if infiltrated with a clear fluid, which could not be pressed out. The bundles of fibrous tissue ran mainly in two directions—some parallel to the surface, and others traversing these perpendicularly, and accompanying blood-vessels. The lymphatics were dilated into irregular spaces or rounded channels. The ducts of the sweat glands were much elongated, owing to the increased thickness of the cutis. Ulceration had occurred in several parts, destroying the papillary body; and micrococci, probably connected with the septic process, were found in vessels in the vicinity of the ulcers. The sciatic nerve and its branches and the anterior crural were about one-third larger than normal; the neurilemma and the surrounding connective tissue were notably thickened, and in some of the fibres the axis cylinders were broken up or wanting. The lymphatic glands were in a state of chronic inflammation. There was also some inflammation of the coats of the femoral artery and vein.

CHLOROPHYLL IN ANIMALS.

SOME biologists have considered that chlorophyll in animals was due to the presence of minute parasitic algae; but this view, entertained by German physiologists, is opposed to various considerations. Chlorophyll has been found in a diffused condition throughout all the tissues, and not merely in the form of little globules, which might be considered as independent organisms. Mr. McMunn read a paper at the British Association in which he defined chlorophyll as that coloring matter or mixture of coloring matters which can be extracted from green leaves by means of alcohol and ether. He had proved that this green coloring matter was present in the intestines of invertebrate animals, and the conclusion at which he arrived was that all the characteristic appearances of vegetable chlorophyll are present in animals, and that such pigments were synthetically built up by and in the bodies of animals.

CONTINUITY OF STRUCTURE IN VEGETABLE ORGANISMS.

The continuity of the protoplasm through the walls of vegetable cells was the subject of a series of papers at the meeting of the British Association at Southport. Mr. Walter Gardiner has embraced in his investigations fifty species of plants, and he found that the cells were placed in communication with one another by means of delicate threads passing through the walls of the cells. For some time evidence has been tending to show the unity of the vegetable individual and the working together of its various specialized organs. In every single property of protoplasm and in the exhibition of every phenomenon the plant and the animal have been shown to be possessed of a common life. The statement that in animal life there is a differentiation of the protoplasm, while in the plant there is only one of cell wall, can now no longer be held. These new facts give us a clearer insight into such phenomena as the downward movement of a sensitive leaf upon stimulation of the action of a tendril to-

wards its support and so forth. Dr. Carpenter expressed the very deep interest which ought to be felt in these communications, because they went to the very fundamental conception of life. We have been coming to perceive, he said, that there are a great many forms of animal and vegetable life which never arrive at the dignity of cell form. This continuity of protoplasm was really just drawing the lower forms of the two kingdoms into closer approximation.

EXERCISE v. BANTINGISM.

OBESITY is a disease—a gradual, yet a true perversion of a normal state, and therefore a disease—which from its continual irksomeness, apart from any worse symptoms, renders those who suffer from it particularly ready to accept any means of relief, reasonable or unreasonable, if only it will ease them of their burden. It would be superfluous to review the various systems professedly based on scientific principles, but really founded too often on fallacious reasoning, which have claimed to achieve this result. When one considers the slow development of this condition, its selection of certain individuals in preference to others who consume the same ingredients of diet, and the other circumstances of those affected, it is clear that there is some inherent state of being or habit of life which, more than mere quality of food, conduces to excessive fat formation. For its safe and effectual treatment, provided that the case be not of so long-standing as to be beyond all treatment, this state must first be understood and regulated. It is well known that whatever interferes with oxidation, with due metamorphosis of digested food within the tissues, is apt to lead to its storage in the form of fat. This is true not only of fat itself, but also, though in a much less degree, of substances—as albumen—far removed from it in the scale of chemical change. Such interference arises, on the one hand, from the ingestion of more food than can possibly undergo assimilation, especially if it be largely composed of carbohydrates; on the other, from insufficient demand for formative material on the part of the tissue elements themselves, and this demand is proportionate to their loss by exertion. It is therefore necessary for health that consumption should be limited as nearly as may be to what is necessary for sustenance, and that discharge of waste and tissue demand should be at the same time encouraged by moderate bodily exercise. But, moreover, the limitation of food must be in its quantity rather than its kind. A certain mixed diet is requisite for healthy growth, and neither fatty, farinaceous, nor albuminoid material can be omitted from it in any considerable proportion without detriment to the general nutrition. If the stout man who desires to be thin will restrict himself to a lean meat diet, taking but a trifling amount of the other more carbonaceous substances after the Banting method, he will indeed lose bulk, but the restriction will not arrest his fat-forming propensity, which still survives, though on reduced fare, and will return to him as soon as he resumes his former mode of living. Moreover, his Bantingism must either underfeed the non-fatty tissues in respect of their most important constituent, carbon, or to avoid this must so overload every organ, but especially the kidneys, with surplus albuminoid excreta as to cause their overwork and degeneration at no distant date. The danger, though still real, is less to men of active habits, but such the obese commonly are not. By this method we seek to avoid one trouble, with partial success, only to fall into another, perhaps worse. While therefore we are ready to

admit that stout persons should be content with a less rich diet than the spare-bodied, we are careful to preserve its essentially mixed character, to limit its consumption in quantity, and to rely for disposal of the products of digestion mainly on regular and methodical physical exertion. There should be no difficulty about this latter, seeing that it may be taken in different forms suited to various ages and constitutional types. Walking, riding, rowing, and for the younger and more robust, athletic exercises of more energetic kinds, are among the most valuable, from their exercising more or less the whole of the muscular energies. Then there are many kinds of amateur work which offer the same advantages. By all such means free play is afforded for tissue changes, for excretion of waste, and for regular and rapid blood circulation. In short, it is necessary for him who would enjoy the ease of an unencumbered person to remember in practice that the laws of supply and demand have a relation to one another as close and as inseparable in the human frame as in the commercial world.

THE MUTABILITY OF BACTERIA.

THE question whether the same germs under different conditions give rise to various diseases has been raised, but not settled. Dr. Carpenter, at the meeting of the British Association, treated the subject from a point of view of natural history. He referred to the facility which the lower forms of life possess of adapting themselves to changed conditions of existence. He believes that the same germs may under altered circumstances produce various diseases, and these opinions he supported by various arguments. The decrease of the virulence of the small-pox which ravaged Europe in the fifteenth century he attributed to the cultivation of the mildest cases which occurred. A severe attack of any particular disease may so affect the system that a disease arises which cannot be recognized as related to that from which it proceeded. Under favorable conditions an ordinary intermittent fever may develop into a virulent form, which is highly contagious. There is in his opinion, very strong ground for the belief that even the innocent hay bacillus may undergo such an alteration in its type as to become the germ of severe disease.

FRUIT AS AN ARTICLE OF DIET FOR THE SICK.

THIS question was lately discussed by Professor Reclam in the *Gesundheit*, and in the course of his remarks he laid stress upon the necessity of properly masticating fruit, as much of the prejudice which exists against its use as a portion of a sick person's diet arises from the fact that it is often consumed in a hasty and consequently injurious manner. He excludes from his dietary scale all fruit which is so hard as to require much exertion in masticating it. As to the choice of fruit, he gives copious details as to the relative proportions of acid contained in different varieties. Plums contain the largest quantity of acid and only a limited amount of saccharine matter, although the taste is deceived in this respect by the other component parts of the fruit in question. Ripe red pears form the other extreme of the scale of acidity.

GRAPHIC RECORD OF MOVEMENTS.

AN ingenious apparatus for graphically recording the movements of the hand and fingers under various conditions has been devised by Dr. Francis Warner. It resembles the indiarubber tubing on the backs of cricketing gloves, designed to pro-

fect the hand from injury; but the tubes are closed, and not jointed; they are connected by means of small conducting tubes of caoutchouc with a series of tambours; with the tubes is also connected an electric apparatus, by which a bell can be rung when a movement is made and a tracing taken. Dr. Warner believes that by observations made with this instrument the mental development of infants may be followed, the amount, kind, and co-ordination of their movements affording information in regard to the internal conditions of their nervous system. He finds that children are, except when their attention is strongly excited, constantly executing spontaneous movements; but such movements fail in adult age, being replaced by the function of "mentation," or thought. When the function of mentation is lessened, as by fever, the excess of movement often reappears in delirium as subsultus tendinum. In many so-called mental conditions the emotions are expressed by the action of the muscles of the face and hand; in other words, we judge of the condition of the nerve-mechanism whose function is mentation by certain nerve-muscular movements, whose exact record and measurement Dr. Warner thinks his apparatus is well adapted to study. The paper is contained in the second part of the fourth volume of the *Journal of Physiology*.

CHOLERA CHEMICALLY CONSIDERED.

THE greater the ignorance which prevails on any particular subject the more numerous are the existing views on that question. An acquaintance with such a variety of opinions possesses a certain kind of interest. M. Ramon de Luna has given expression to his views on cholera at a recent meeting of the Académie des Sciences. He believes that the cause of cholera is always to be found in the atmosphere; that it exerts its action exclusively through the respiratory passages; that it is especially during the passive condition of the individual, particularly during sleep, that its incubation takes place; that the microbe or ferment acts chiefly on the blood-corpuscles, preventing proper oxidation, and so leading to gradual suffocation; that the only remedy which was ascertained to do any good was the inhalation of the fumes of nitrous acid mixed with air; and that the same agent is of prophylactic value against cholera. These conclusions are given as the result of practical successful experience.

VARIATIONS OF THE URINARY CHLORIDES.

No one will deny that a more frequent examination of the constituents of the urine might lead to the acquisition of fresh knowledge. Even in our public clinical institutions the systematic estimation of the most important urinary constituent is not regularly carried out. A complete clinical account of the changes in the urine which attend the active stages of the rachitic process would probably be attended with important additions to medical science. Indeed, the same may be said of most acute diseases. In ordinary medical attainments perhaps the only piece of information with regard to the chlorides of the urine consists in the knowledge of the fact that there is a remarkable diminution of this ingredient in acute pneumonia. M. Barot has done well to draw attention to this unploughed field of clinical medicine. He has devised a simple apparatus for the purpose of estimating the chlorides. A small flask is furnished at its inferior extremity with an ampulla capable of holding just one cubic centimetre of urine. A pipette is obtained, gauged in tenths of a cubic centimetre. Another little flask containing

a solution of argentic nitrate is used from which the pipette may suck up some of its contents by means of a ball of caoutchouc. A cubic centimetre of urine is first treated with a solution of potassic chromate. The solution of nitrate of silver of known strength is then dropped in by means of the pipette. The whole of the chlorides in the urine have been obtained as soon as the *café au lait* precipitate of chromate of silver appears. M. Barot found that the normal amount of chlorides in the urine was eleven grammes for every litre, consisting of ten grammes of chloride of sodium and one of chloride of calcium. In tuberculosis it was estimated that seventeen to eighteen grammes of chlorides per litre were discharged. But a diminution of the chlorides is of greater import, especially in acute affections. In pneumonia, when the temperature is much raised the fall in chlorides is considerable. This diminution was not noted in broncho-pneumonia. But in the pneumonia of typhoid fever at the onset of death the chlorides completely vanished.

DEATH FROM COLD IN MAMMALS.

THE behavior of protoplasm under the influence of different degrees of temperature is still insufficiently known. We are familiar with the general facts that excessive heat or cold brings about death, and that fever is attended with increased tissue changes; and in some measure we understand the kind of way in which this happens; but that is all. MM. Richet and Rondeau have studied the influence of cold on some mammals. They have adopted a method by which the temperature of the animals has been gradually lowered. Dogs resist cold so well that no experiments were made on them. Rabbits were chiefly employed in these investigations. These animals were shaved and surrounded with flexible pewter tubes, through which cold water was made to circulate. When the temperature of the body was lowered to 25° C. respiration began to be ineffectual. The rhythm was not modified; but the amplitude of the inspirations was chiefly diminished. The functions of the nervous system were much abated when the temperature fell to 17° C.; they were not, however, abolished. Reflex movements were obtained, even when the temperature sank to 15° or 14° C.; and the observers believe that the excitability of the nervous system disappeared not directly on account of the cold, but probably from arrest of the circulation. Spontaneous movements disappear before the reflex acts. The reflex from the cornea went before those from the lower limbs. At 16° C. the reflexes were remarkably slow and like those in animals with a cold circulation. Sensibility to pain was not abolished even at the temperature of 16° C. Cold gradually slowed the cardiac action. The form of the contraction at 17° C. was like that of the heart of the tortoise. Systole commenced at the auricles, and by a slow vermicular movement passed on to the ventricles. Even although death had been apparent for half an hour, the animal could be restored to life; so that vitality can be recalled half an hour after the cessation of respiration and circulation. When the temperature was 19° C., it took more than ten minutes to asphyxiate the rabbit by blocking the trachea. We may conclude from this that tissue metabolism is correspondingly slow. The same animal was suffocated in four minutes at a temperature of 32° C. MM. Richet and Rondeau commented on the similarity between the vital processes of hibernating animals and those of rabbits thus experimented upon, in which a condition, so to speak, of artificial hibernation may be induced.

ANIMAL ELECTRICITY.

DR. McKENDRICK, so well known for his physiological researches, delivered an able and interesting lecture on Galvani and Animal Electricity before the Southport meeting of the British Association a short time since. In summing up, the lecturer said that all these electrical changes were really expressions of the vital changes occurring in living tissues under the action of stimuli. It was no part of the functions of nerves, muscles, or of the retina of the eye to produce electrical currents under the action of their relative stimuli; but such currents indicated chemical changes in the organs or tissues. For example, the contraction of a muscle is a movement following or consequent upon many chemical changes, among the results of which were the production of heat and differences of electrical potential. Thus, there was no special production of electricity except in the cases of electrical fishes, and possibly of some other animals. In most animals, including man, the production of currents was an incidental phenomenon, indicating chemical operations and nothing more. Besides, the currents so produced were feeble and evanescent and bore no relation to the general well being. Consequently, all attempts to influence the living body by magnets had no rational basis. It need hardly be said that the so-called phenomena of animal magnetism are of an entirely different kind from those discussed. These are of a subjective character, dependent on peculiar states of the nervous system, having nothing whatever to do with electricity or magnetism; but still in a sense they are phenomena as real as those of physical science. Their subjective character, however, renders them specially difficult of investigation, and consequently they are more liable to fall into the hands of the charlatan.

ALLEGED DISCOVERY OF THE CHOLERA BACILLUS.

It has been announced that the German Commission under Dr. R. Koch, which was sent in August last to Egypt to investigate cholera, has reported to the German Chancellor that its labors, so far as Egypt is concerned, are at an end; but, owing to the important results so far obtained, they have sought and obtained permission to continue their researches in the home of cholera—India. The Commission (which consists of Dr. Koch and his two assistants, Drs. Gaffky and Fischer) has therefore left Alexandria for Cairo, *en route* for Bombay. The methods pursued by the Commission in this inquiry have been those which have been so fruitful of results in recent researches into the etiology of infectious diseases. Although they failed to detect any specific micro-organism in the cholera dejections or intestinal contents, a peculiar kind of bacillus, much resembling in its characters that of glanders, has been discovered by them in the intestinal walls, the post-mortem examinations being made sufficiently early to preclude the idea that these organisms were connected with putrefaction. The cessation of the epidemic in Egypt has not only deprived them of the material necessary to the further prosecution of this research, but has left them without means to verify the possibly specific nature of these bacilli by the method of inoculation in animals. Sufficient has been gained, however, to justify their request to be allowed to proceed to the centres of the disease, where they will enjoy great opportunities for the prosecution of their work. It must be a matter of congratulation, not only to Germany, but to the whole world, that at last there is some hope of the true nature of cholera being brought to light, and that the method of research initiated by Pasteur and pursued by Koch, which has done so much of late years to en-

large our knowledge of many hitherto obscure affections, seems likely to lead to results of immeasurable importance.

It has not yet been announced what results have been obtained by the Commission sent out by the French Government at the instance of Professor Pasteur. The lamented death from cholera of Dr. Thuillier, the leader of this Commission, may have seriously affected its labors; for whilst the German Commission is already on its way to further continue its research, the surviving members of the French Commission have returned home.

One important lesson is taught by the work of the German Commission which the English Government might take to heart. It seems probable that the discovery of the true nature of the virus of cholera will be effected in England's greatest dependency, but not by Englishmen. Is it not something of a humiliation and a reproach that this country, which has generally posed as the centre of sanitation and preventive medicine, should possess no such department as that over which Dr. Koch presides, and that it possesses no means of equipping a scientific commission like that which has been sent from Berlin? It is high time that the ground for such a reproach should no longer exist; and that England, with her vast resources, should not suffer researches of such vast importance to be left in the hands of private individuals.

EARLY SYMPTOMS OF GENERAL PARALYSIS OF THE INSANE.

In a paper read at the annual meeting of the Massachusetts Medical Society, Dr. W. B. Goldsmith, of Danvers, analyzed the initial symptoms recorded in the histories of 100 cases of general paralysis of the insane, in which he points out the exceptional occurrence at an early stage of the disease of any well-marked characteristics; that physical and mental symptoms usually appear nearly synchronously, the most frequent and characteristic being defective articulation. He also concludes that changes in the pupils and disorders of the gait are less frequent, and have less value in diagnosis, than is usually ascribed to them. He found the patellar tendon reflex to be markedly supra-normal in nearly 25 per cent. of general paralytics, the presence of this symptom being of much value in corroborating diagnosis, its absence having, however, no significance. Hallucination, or impaired function of the special senses, is very rare as an early symptom; nor had he noticed in any case the diminution in the sense of smell, thought by Voisin to be very frequent in the early stages. In twenty of his cases, the first "motor" symptom consisted in convulsions or loss of consciousness; and he urges the importance of careful inquiry on this head. Among mental symptoms, the marked exhilaration with delusions of wealth and greatness, usually considered to be characteristic, was present early in less than one-fourth of the cases; the more frequent change is simple failure of mental capacity and activity, and mental depression.

OPERATING BY THE ELECTRIC LIGHT.

A SHORT time since the electric light was used in the operating-room of the Royal London Ophthalmic Hospital, Moorfields. Mr. Lawson, Mr. Couper, and Mr. Tweedy each performed extraction of cataract, as well as other operations, including iridectomy for acute glaucoma and discission for soft cataract by the aid of the light. The day was well suited for the trial, as the early part of the morning was very foggy, and so dark that the operations could not have been performed without

the aid of artificial light; later on the fog cleared off, and the room was then darkened, and several operations were satisfactorily completed with the aid of the new light. The excellence of the light for operations on the eye was well demonstrated, and we have no doubt that it will be shortly in use in most hospitals for operations by night or on dark days. The light was furnished by a platinum wire incandescent burner placed in a metal case, with a polished reflector behind and a lens in front of it. This was fixed on a movable stand, which could be carried in the hand of the assistant. With wires the lamp was connected with a bichromate of potash battery with four two-quart cells, each cell really holding only about one quart and half a pint of the solution, so as to allow of the immersion of the plates. The battery was furnished by Messrs Weiss, of the Strand.

PURE WATER FOR CATTLE.

THE question of "pure water for cattle" which was raised in the columns of *The Times* a short time since is one of such vital importance to farmers that we can only wonder that it has never been seriously discussed before. It takes time, to be sure, for the teachings of science to penetrate to all members of a community; but it has long been common knowledge that impure water is not only a vehicle of contagion but a source of disease in man, and there can be no question that it is an equally fertile source of disease among cattle. If common sense could only be applied in this matter, we should hear less of the ravages of foot-and-mouth disease, and probably of other epidemics of contagious disease in animals, not to mention the numerous forms of parasitic disease, of which the "sheep-rot" is an instance; and if, as we gather from the statements preferred by the writers referred to, the present Acts contain no provisions for enforcing rules as to the supply of water to herds and flocks, it is time they were amended in that direction. The *native* reply which one correspondent alleges is mostly given by the farmer when asked if he is not afraid to let his cattle drink at one of these abominable roadside yards—"Bless you, sir, they delight in it, they prefer it!"—is a sample of bucolic ignorance which is probably not overdrawn. No doubt in many rural districts the remedy for this state of affairs would be a matter of great trouble and expense; but, as the question of the water-supply to the inhabitants of such places has been, or ought to have been, solved, there is no reason against its extension to the case of cattle. As a mere matter of economics the effort should be made, and the results would soon convince the most sceptical.

SCIENTIFIC HANGING.

THE recent selection of a successor to Marwood in the office of common hangman naturally draws attention to the method of execution by hanging. It is of no immediate practical avail to discuss whether hanging is the best mode of inflicting capital punishment; but it is important to consider what precautions should be taken to render the process of extinguishing life by hanging as certain, quick, and painless as possible. Hanging may be fatal in three ways. First, by compressing the larynx or windpipe, and thereby producing asphyxia. This mode of death is comparatively slow and extremely painful, consciousness being only gradually lost, and the obstruction to the entrance of air causing distressing voluntary and involuntary efforts. The second method is that of compressing the vessels of the neck and produc-

ing intense venous congestion of the brain, with possible capillary hæmorrhages in places. At the same time, compression of the vagi nerves may induce inhibition of the heart; this would be generally combined with asphyxia, and would tend to quicken that process. The third way in which hanging can kill is by instantaneous injury to the central nervous system. This can only happen when the head is displaced from the spine, or a dislocation or fracture of the upper cervical vertebrae occurs; in either case the trunk falls forwards, and the arch of the atlas or of one of the lower cervical vertebrae crushes the spinal cord. In this case death must be painless and instantaneous, its mechanism being that long familiar in the "pithing" of animals. Dislocation can only be produced when the ligaments of the spine are subjected to severe and sudden strain, and the amount of strain necessary will vary considerably with different individuals. It will require in all cases a "long drop," and care must be taken that the rope does not catch in any part of the person, and does not break. It is very desirable that the exact mode of hanging should not be allowed to depend upon the caprice of a common hangman, and the Home Office might well draw up instructions to be observed in all executions, with a view of ensuring that the sentence of the law shall be carried out without unnecessary pain, and that justice shall be tempered with mercy.

Correspondence.

"Audi alteram partem."

HOMŒOPATHY.

To the Editor of THE LANCET.

SIR—It is a subject for much regret that anyone, more especially the editor of our leading medical organ, should deem my offer to St. George's Hospital to be disrespectful to the medical profession.

No one more highly appreciates the honorable, humane, and learned character of medical men than myself, and amongst those in orthodox practice I am proud to number many of my oldest and dearest friends. Nevertheless, it is impossible to ignore surrounding facts. At the present moment some thousands of duly qualified medical men are following the system of Hahnemann, while hospitals in every civilized country are publicly testing its value. Further, the most popular work on therapeutics amongst the rising generation of students—Sidney Ringer's—owes much of its fame to the promulgation of a series of specifics, mostly traceable to homœopathy—a system which is allowed, even by its greatest opponents, to be largely permeating general practice. Impressed with the excellence of much that is advocated by the homœopathic school, and still more impressed by the practical results constantly brought under notice in hospital and private practice, the writer was induced to endeavor to bring about a public test of the efficacy of the new treatment, and observing that a number of beds were unoccupied in St. George's Hospital from lack of funds, the offer referred to was made. It will hardly be necessary to add that I have no interest in any system of medicine. My only desire is that that which is most efficacious in the treatment of disease should be adopted; and I know of no better plan for discovering this than the establishment of test beds under proper conditions and for a sufficient period to avoid the possibility

of chance. If the result should be adverse, it will do more to discourage homœopathy than reams of print; if otherwise, surely the members of a progressive profession would be the first to acknowledge, and rejoice at, such an outcome of the experiment.

I am, Sir, yours faithfully,
WM. VAUGHAN MORGAN.

The Boltons, S.W., Sept., 1883.

* * Our correspondent does not seem to be aware that homœopathy scarcely exists as understood by Hahnemann. Its most popular exponent in London has published a new doctrine of therapeutics, directly contradicting Hahnemann's fundamental principle. We published last week the suggestion of a Hahnemannian journal, to drop the word "homœopathy" out of existence, as the only means of averting the imminent dissolution of the school. We are quite aware that there is a section of the public that believe in homœopathy; but they are attended by those who have abandoned all its essential principles while still retaining the name. The argument that homœopathy only needs a trial is quite untenable. It has been on its trial eighty years—as long, in fact, as vaccination. While vaccination is accepted by the whole world of scientific and rational men, homœopathy is without a chair in any university of Europe, and it is proposed by its own leaders to drop the very name. The attitude of scientific medicine to it *ab initio* is thus thoroughly justified. The attempt to take shelter under the name of Dr. Sidney Ringer is now rather a favorite device of homœopaths. But it will not save either their scientific or their moral position. Dr. Ringer takes medicines as he finds them, and investigates their action in health and disease unhampered by authority, and he does not trade on a name.—Ed. L.

CASE OF CHLORAL POISONING.

To the Editor of THE LANCET.

SIR—Thinking that the following case may be of interest from a toxicological and therapeutical point of view, I am induced to send you the account of it.

The patient, a gentleman twenty-six years of age, was suffering extreme pain from syphilitic rupia, for which I prescribed the following mixture in order to relieve his pain and induce sleep: Chloral hydrate, six drachms; bromide of potassium, half an ounce; orange water, four ounces; two drachms of the solution to be taken at bedtime. The patient (wiffully) swallowed the whole contents except one ounce. The draught must have been taken about midnight, and the patient was not seen till next morning at eight o'clock, when his mother saw him, and she, thinking he was sleeping naturally, did not disturb him. He was again seen at ten o'clock, when an effort was made to wake him, which, however, was unsuccessful. I was then sent for, and on my arrival at half-past twelve he was in the following condition: He was lying on his back; eyes and mouth wide open; conjunctivæ injected and pupils contracted; congestion of his capillary system generally; breathing heavily; complete muscular relaxation and reflex action abolished; pulse slow and full; temperature 102°. He was with some difficulty aroused, but by continuous efforts was he awake

and so far aroused as to be persuaded to swallow some strong black coffee. By both vocal and physical means he was at length aroused to a sense of his position; but as soon as these efforts were relaxed he relapsed into the drowsy condition. Strychnine was then administered, and instructions given to keep him awake. In three hours' time he was completely conscious, and felt quite well except for a feeling of lassitude. The strychnine was repeated, and during the afternoon he was quite prepared for dinner. His temperature fell 2°, and his pulse regained its natural strength and volume. His return of consciousness, he himself states, was just subsequent to his having the coffee, and his prior loss of consciousness was immediately after swallowing the chloral. To my positive knowledge no narcotic had been taken for at least six months previous to this occurrence, but at that time he could take four grains of solid opium. Chloral he has had on two occasions, in sixty grain doses. Bromide he never had before. On this occasion he swallowed 270 grains of chloral, or nearly five drachms, combined with three drachms of bromide. Such is the history of the case; its full value is lost of course, owing to the length of time elapsing between the taking of the poison and the notifying of the symptoms. Ten hours had elapsed before my seeing him, but I think had he been allowed to continue his slumbers undisturbed the result would have been the same—namely, complete recovery. The poisonous effects must have been much more decided during the hours immediately succeeding his taking the draught.

Dr. Levenstein reports a case where the dose taken was six drachms, and recovery ensued. But in his case twenty-four hours elapsed before consciousness was restored, and that only after continuous treatment from the first hour of the poison being taken.

I am, Sir, yours obediently,
ARTHUR MECHAN, M.B. C.M. Glasg.

Glasgow, Oct., 1883.

To the Editor of THE LANCET.

SIR—I have read with interest Mr. Mechan's letter on the above. The action of chloral is so uncertain that I have the greatest hesitation in prescribing it, even in obstetric cases. It is in these cases that I consider its employment justifiable, as chloroform is better borne after it than after any other sedative, for obvious reasons. But when we have the choice of a sedative, and there is no special reason for using chloral, as in Mr. Mechan's case, would it not be safer to prescribe bromide of potassium alone, or with some such addition as hyoscyamus or belladonna? I am not casting any reflection on Mr. Mechan, for he did not order his patient to take three-quarters of the whole mixture at one gulp, nor did his patient die; but I am simply insisting on the danger of using the drug at all when it can be avoided, which, in my opinion, is nearly always.

In 1880 I published notes of a case of Poisoning by Chloral Hydrate in THE LANCET, and although the dose taken was 100 grains less than that taken by Mr. Mechan's patient, the symptoms were very serious. The drug, I need hardly say, was taken without my knowledge. More than once I have known even small doses so badly borne that I look on chloral as a very treacherous friend. If taken habitually, the damage done to the brain is very great, and the habit is very difficult to abandon.

In the case of neuralgic females (usually weak-minded ladies) chloride of ammonium is far more

valuable and far less harmful, but they persist in taking chloral.—I am, Sir, yours truly,

A. ST. CLAIR BUXTON, F.R.C.S.

The Grove, W., Oct. 28th, 1883.

CASE OF ANENCEPHALUS AT THE ROTUNDA.

To the Editor of THE LANCET.

SIR—While acting as clinical assistant at the above hospital, I was called to a case of doubtful presentation in the extern maternity, which I diagnosed to be one of anencephalus foetus. I beg to lay before your readers some important points in the diagnosis of such cases, with special reference to the case in hand.

Mrs. G—, aged thirty-eight; third pregnancy, full term; somewhat anæmic, and fairly well developed; previous health good; two former confinements tedious, the forceps being used; last confinement three years ago; both children living, healthy, and very well developed; husband tall and well formed. On external examination the abdominal walls were found to be extremely lax and oedematous; the membranes had been ruptured just before by the gentleman in attendance, as the distension was very great from hydramnios, and the first stage had been very prolonged; sixteen pints of liquor amnii were allowed gradually to escape. By palpation the back of the foetus could be clearly made out on the right side, and the small parts to the left posteriorly; the cranial end of the foetus could be grasped over the pubes, entering the pelvis. The foetal heart was best heard to beat (at the rate of 120 per minute) in the right hypogastrium. The os uteri was found to be almost fully dilated, and what seemed a face presented in the second position. The nose was felt and the eyeballs markedly protruding; the fingers, passing forwards, dipped over a sharp orbital ridge into a depression corresponding to the calvaria, with a small fleshy protrusion in its centre (the exposed medulla), which, when pressed on, caused vigorous spasmodic movements of the foetus. The mastoid processes were very prominent, and the distance between them small. The patient was exhausted, having been in the first stage fully twenty-three hours. A binder was put on, and the uterine efforts aided, but the shoulders seemed to be arrested at the brim. Dr. Henry, the senior assistant-physician, was sent for, and a drachm of liquid extract of ergot administered, immediately after which she was anesthetized, the forceps applied, and a safe delivery effected. The foetus was large, and, with the exception of spina bifida, was well developed from the shoulders to the lower extremities; the umbilical cord was shorter than usual, and constricted the middle of the left arm so tightly as to leave a marked groove one-third of an inch deep, and, strange to say, the distal portion of the limb was well developed, and to all appearance similar to its fellow. Another drachm of ergot was administered at the end of the second stage. There was slight hemorrhage. The placenta was retained and adherent, having a very large uterine attachment, and was detached by the introduction of my left hand into the uterus after gradual dilatation of the os.—I am, Sir, yours, etc.,

H. D. McCULLOCH, M.B. & C.M. Glas.

Dublin, Sept. 11th. 1883.

THE ADMINISTRATION OF ANÆSTHETICS AT HOSPITALS.

To the Editor of THE LANCET.

SIR—May I take the liberty of addressing you on what I venture to call an evil in hospital manage-

ment? It is the practice at some hospitals to bring up patients into the operating theatre and give them an anæsthetic before a crowd of students, etc. I believe such a course is frequently unnecessary, and I am convinced it is cruel. I cannot find any good reason why patients (and I refer especially to women) could not have an anæsthetic given before they are placed upon the operating table. What happens now? A woman, naturally nervous and anxious about the coming operation, is brought up and placed upon the table; she looks round to see where she is, and finds herself face to face with a more or less crowded theatre, and she then awaits the arrival of the chloroformist. The surgeon in charge explains the case to the students present as she is passing under the influence of the anæsthetic, or occupies the time in conversing with courteous amiability to the "distinguished foreigner," or a "fellow practitioner." Could not the anæsthetic be given either in the ward or in a special room for that purpose? I complain of an evil that could be easily remedied, and consider that a woman in a well-conducted hospital ought to be able to undergo an operation without knowing she has left the ward.

The outside public, though ready to obtain advantages from hospital treatment, are ever watching for some loophole for complaint or scandal, and the proper authorities have it in their power to show them that the study of surgery does not produce any indifference to the sensitive feelings of our nature, and to point out to those who assume to themselves a monopoly of humane feeling that they are ever ready to remedy a source of suffering or to save the infliction of unnecessary pain. Hoping you will have room for these few lines in your columns, believe me, Sir, your obedient servant,

GEO. H. DE'ATH.

Guy's Hospital, S.E., Sept. 26th, 1883.

"CHLOROPHYLL IN ANIMALS."

To the Editor of THE LANCET.

SIR—Readers of the report of my paper, read at the meeting of the British Association, on the "Occurrence of Chlorophyll in Animals," as it has appeared in most of the medical journals might be easily led to believe that my conclusions are based on insufficient data, as, from the report, I am stated to have based my conclusions on the occurrence of that substance in the "intestines" of invertebrate animals. I, however, have not done anything of the sort. Finding an iron nail in a horse's stomach would not be considered a proof that a horse had a blacksmith's forge in that situation.

I based my conclusions on the fact that I could extract a chlorophyll pigment out of the appendages of the enteron—e.g., "liver" of *Helix*, *Limax*, *Anodonta*, *Mytilus*, *Astacus*, etc.; pyloric cæca of *Asterias*, *Uraster*, and intestinal appendages of *Echinus*, and so on, this pigment being present under such conditions, and in such a state as to preclude the possibility of its being derived directly from food chlorophyll. Moreover, I stated that I had repeated certain experiments of Pocklington's, published in the *Pharmaceutical Journal* for 1873, on the wing-cases of *Cantharides*, and extended his observations in such a manner as to prove beyond doubt that the wing-cases contained chlorophyll identical with that of plants. Although the reports in some of the newspapers might lead anyone to suppose that some doubt must be attached to my conclusions, I may recall to mind that Professor Lankester and Dr. Sorby have proved that this pigment is found in *Spongella*,

Hydra, and perhaps in other invertebrate animals. The spectrum of chlorophyll alone and with acids is so peculiar—when the whole series of bands is present—as to leave no doubt in the mind of a practiced observer whether he is dealing with chlorophyll or not. What I endeavored to prove, however, in addition to the proof of identity of animal and vegetable chlorophyll, was the fact that this substance is built up by the animal, and is not due to “symbiosis” in those cases which I have observed, as recent German writers have tried to show that in all cases where chlorophyll has been found in animals the presence of parasitic algae has been the cause of its being present. The coloring matter observed by me in the appendages of the enteron of the above-mentioned animals I have named, for obvious reasons, “entero-chlorophyll,” and the results of these observations, as well as the spectra of the various solutions, will be found in the Proceedings of the Royal Society, No. 226, 1883.

I am, Sir, yours faithfully,

C. A. MACMUNN, B.A., M.D.

Oakleigh, Wolverhampton, October, 1883.

SULPHUR FUMIGATION IN CHOLERA DISTRICTS.

To the Editor of THE LANCET.

SIR—I observe that you mention the plan of disinfection of the cholera districts in Egypt by sulphur fumigation. Since 1872 I have steadily advocated this method of disinfection in India by means of sulphurous acid, and have now the pleasure to forward the last edition of my pamphlet on the subject. Since its publication I have received additional testimony of its efficacy. At Bombay, during the last epidemic there, it was adopted, and the disease ceased almost immediately after the fires were kindled, with an immunity from it as had not been known for five years.

In 1882, when cholera was very virulent at Dumdum, and in all the villages near the cantonments, till at last it appeared in the Sudder Bazaar, sulphur fires were adopted extensively. The disease ceased in a most marvellous manner, and not a single case occurred in the Border Regiment stationed there. Sulphur fires should be kept burning through the streets for several days, at distances of twenty or thirty yards, where cholera is virulent. Every house where cholera has occurred should be evacuated and thoroughly disinfected with sulphurous acid, and the floors and walls disinfected with carbolic acid or phenyle. Furniture should be taken out or covered, as the fumes might fade the colors. A very easy means of disinfection of houses can be effected by the inhabitants evacuating them temporarily, and burning sulphur for a few hours, or in different rooms alternately.

I trust you will give me the credit of being the first to initiate this plan of disinfection by noticing my pamphlet in THE LANCET. Some years since I forwarded you a copy, which was made mention of in a short paragraph. I quite agree with you that street fumigation is not sufficient, but it can be pushed still further by burning sulphur in all infected houses, streets, or gullies. Liquid sulphurous acid might be sprinkled on walls and floors. The measure has been so entirely effectual in India that I feel sure you will do me the justice to review my brochure, for the benefit of the profession and the public.

I am, Sir, yours very truly,

JOHN E. TUSON, M.D.,

Deputy Surgeon-General, Presidency District.
Calcutta, August, 22nd, 1883.

“TREATMENT OF CHOLERA”: A NEW METHOD PROPOSED.

To the Editor of THE LANCET.

SIR—About two months ago I took up my pen to address you on the subject of the treatment of cholera, but relinquished the idea for fear of trespassing on your valuable space. Now that communications under the heading of this letter are well-nigh exhausted, will you, should you deem my letter worthy of a place in your esteemed journal, kindly allow me a small space to mention a method of treatment which has occurred to me, and which I believe might be tried with advantage should cholera again visit these shores? The method I refer to is medication per vesicam. We are all aware of the empty and contracted condition of the bladder, and of the great demand made on the system for its fluids in cases of malignant cholera; and considering the small quantity of fluid we can administer to the sufferer by the mouth or by injection (subcutaneous and intravenous), I think we have in the bladder cavity a means whereby we can supply that deficiency of fluid, and at the same time administer such remedies to the patient as our judgment dictates. I do not believe that in health any great absorption can or does take place; but in cholera I believe it to be otherwise, and that fluid injected into the bladder would be speedily absorbed. Such remedies as chloral hydrate and thymol (strong antiseptics in very dilute solutions) could easily be administered, combined with sedatives (e.g., morphia) or stimulants if necessary, the fluid so injected being first raised to 98° or 99° F.

It is my firm belief that non-irritant fluids could safely be administered by way of the peritoneal cavity; but no one in his senses would attempt such a method without first experimenting on the lower animals (now, alas! in the hands of a favored few). Should, however, future research enable us to overcome the dangers of injecting suitable remedies into the peritoneal and other serous cavities, we shall then have solved the problem of directly acting on the great lymphatic vessels, and so influencing various septic diseases, which we know to have their origin, by open mouths, in such serous cavities.

I am, Sir, your obedient servant,

G. CARRINGTON PURVIS, M.B., C.M. Ed.

Loughboro'-road, Brixton, S.W., Oct. 9th, 1883.

LEPRA VULGARIS.

To the Editor of THE LANCET.

SIR—The following case of the above malady came under my notice whilst resident surgeon at the Clayton Hospital, Wakefield, and was under the care of Dr. Wright. The case was of three years' standing, and had been treated by several different medical men during that time, without any marked improvement. The patient was first treated by us with chrysophanic acid externally and alkalies internally, without any signs of improvement, for three weeks. He was then treated by remedies recommended by the late Anthony Todd Thomson, and was cured in three weeks.

W. B.—, aged twenty-one years, single, coal miner, was first seen on July 5th, 1883, in the out-patient room of the hospital; he was then found to be suffering from an attack of lepra vulgaris in an extensive form. There were patches of eruption upon his head, body (back and front), and upper and lower extremities (extensor surfaces only); the parts which were free were the face and the flexor surfaces of the extremities. The patches

varied in size and shape, some being three and four inches long and two broad, and others from a line to an inch in diameter. Family history good. The patient had scarlet fever when young; but no other illness up to the present one. Three years ago he first noticed a scaly eruption on the back of his elbows, which quickly showed itself in all the parts named above. From this time up to his coming to the hospital he has been under the treatment of several medical men, but has never received any benefit. For three weeks he was treated as an out-patient, and ordered to apply chrysophanic ointment night and morning, and prescribed half-drachm doses of bicarbonate of potash three times a day. He was then admitted into the hospital. His hair was out quite short, and linseed poultices were applied to the scalp to soften the scales, a hot bath was also administered. He was then ordered the following remedies:—Hydrarg. biniod., gr. iv.; arsenici iodidi, gr. ij.; conii extracti, 3 i.; ft. pil. xx., i. t. d. Dec. sarsæ co., 3 ij., inter pilularum doses singulos. Calomelanos, 3 i.; ungt. picis, 3 iv.; cetacei, 3 i.; ft. ungt. utend. h.s.s. quotidie.

In a few days the eruption showed marked signs of improvement, and in three weeks gradually disappeared, when the treatment was stopped, and the patient was discharged. He has since presented himself several times in the out-patient room, without any return of his complaint.

I am, Sir, your, etc.,

D'ARCY B. CARTER.

Late Resident Surg., Clayton Hosp., Wakefield.
Shipley, Yorkshire, Oct. 8th, 1883.

"INTERMITTENT CHYLURIA."

To the Editor of THE LANCET.

SIR—I have just seen a request in your journal by Mr. E. Parnell Griffiths, M.R.C.S., concerning the treatment of a case of intermittent chyluria. According to the latest studies of Manson, we are justified in supposing chyluria to be developed from the obstruction produced in the lymphatics by a swarm of immature embryo filariæ. In other words, the maternal parasite occasionally aborts, and the abortive products have too great dimensions and are of too unwieldy a shape to pass through the fine lymph-vessels into the circulation, as do the fully developed thread-like parasites. As soon as these obstructions are overcome, the patient in question is freed from the chylous urine, but so long as the original parasites infest him, so long is he subject to a recurrence which may at no distant date become permanent. If, therefore, the source can be removed, this recurrence will be abolished, so that the question of treatment is confined to what will destroy the parasites *in situ*. Without entering into the rationale or discussing the *modus operandi*, I have only to suggest that in my hands in the West Indies the salicylate of iron proved successful in those cases which occurred in my practice. I append the formula, which might otherwise not be easily obtained:—Sulphate of iron, six drachms, twenty-four grains; salicylate of soda, one ounce; acetate of soda, five drachms, twenty grains; water one pint. Each fluid ounce of the above is equal to thirty grains of salicylate of iron. Dose, one to two drachms. It may be combined in any mixture with acetate of potash, spirit of nitrous ether, digitalis, etc. It may be used in erysipelas combined with a diaphoretic instead of tincture of chloride of iron. In this disease use half-ounce doses. Salicylate of iron is thoroughly incompatible with ammonia and its preparations. In this preparation the patient not only has the

germicide effect of the salicylic acid, but the tonic action of the iron, which is always indicated, and that in a form easily assimilated, and which may be made easy and pleasant to take.

I am, Sir, yours, etc.,

J. H. ARTON, M.D.

Winnipeg, Manitoba, Sept. 17th, 1883.

ENTERIC FEVER AND OTORRHOEA.

To the Editor of THE LANCET.

SIR—In connection with Mr. Coveney's inquiry, the following notes of a case that occurred in my practice may be worthy of insertion.

On the first day of illness a bad shiver, earache, and general malaise, with pain in joints until the fifth day were reported. On that day a blister was ordered behind the ear on account of excessive pain. On the seventh day, the earache being much better, sudden delirium supervened at 3 p.m.; temperature, 103.6°. At 11 o'clock the same evening a neighboring practitioner thought the case might be typhoid. On the eighth day a London consultant gave a guarded opinion, inclining to the idea that it might be ear trouble, recommending careful watching, and an aurist's opinion if the patient became worse, with a possible view of opening mastoid cells. On the tenth day the patient was carefully examined early in the morning, and bathed by nurse; no spots seen. At 3.30 the same day, at the wish of friends, an aurist examined the patient, and detected nothing the matter with the ear; but on examining the abdomen a large quantity of typhoid spots were found. There was a good deal of delirium, but the temperature except on the seventh day, as above noted, rarely exceeded 102° at night. I should mention that until the sudden invasion on the seventh day the motions were not at all suggestive of typhoid, though carefully examined. The history obtained pointed to frequent ear trouble from infancy, although a case of typhoid had occurred within a short distance where the patient had been staying. There was no discharge from the ear on this occasion, though there had been previous attacks of otorrhœa. I have heard of typhoid following otorrhœa, but do not speak from personal experience. I classified the above case with typhoid, commencing with meningitis (*vide* Quain's Dictionary of Medicine).

I am, Sir, your obedient servant,

W. P.

Oct. 10th, 1883.

ROTHERN OR RUBEOLA.

To the Editor of THE LANCET.

SIR—From October, 1879, to March, 1880, I had to deal with an outbreak of rothern. Measles and scarlatina coexisting at the time gave me an opportunity of contrasting and comparing the diseases and their symptoms. The following summary of the characteristics and symptoms of rothern, taken from a paper I read at the Cork Medical Society in May, 1880, may not be uninteresting at the present moment:—

"An incubative stage of a fortnight, the disease beginning with pains in the limbs, headache, and stiffness in the neck; the short pyrexial period, the rash appearing in most instances in twenty-four hours, beginning on the face and spreading downwards over the entire body, first appearing as a papular eruption like strophulus, then assuming a measles character, and finally, the spots coalescing, produced an appearance resembling scarlatina. It generally took about three days before the body was entirely covered with the rash,

during which time the fever was at its height. The rash then faded as it began, from above downwards, and with it all feverish symptoms. The pulse ranged from 100 to 105; the temperature sometimes reached 102°; and in every instance there were headache and vomiting, sore-throat without any ulceration, cervical glandular enlargement, with occasional tenderness. There were no thoracic complications, no catarrh or coryza, and no sequelae." In many instances there was conjunctival injection, photophobia, and a most unpleasant itchiness over the entire body, with profuse perspirations. The great majority of the cases were children.

I am, Sir, yours truly,
D. D. DONOVAN.

Cork, 1883.

"THE CHEMICAL LUNG."

To the Editor of THE LANCET.

SIR—Will you kindly inform me if Dr. Neale's "chemical lung" has been found practically useful in rendering agreeable the air in small hospital wards? If the expense of charging chemicals is high regarding a modest institution? And who is agent for the sale of them in London?

I am, Sir, your obedient servant,
E. A. STEPHENSON, M.K.Q.C.P.I.

Clareville, Oct. 15th, 1883.

*The only exhaustive experiment hitherto made has been in the Mission-room, Lisson-grove. The experiment at Aden Hospital was, we believe, most satisfactory. Mr. Dodd, 57 Burton-crescent, will supply every information. The cost of charging would not exceed 1s. a week for an ordinary small hospital ward, and would supply an atmosphere free from all impurities, chemical and organic.—
ED. L.

News Items, Medical Facts, &c.

VIVISECTION FOR FOOD PURPOSES.—We sometimes hear the ruthless foes of scientific research by experiment on living animals denounce the medical profession as unequalled in the cruelty of its instincts. What shall we say of the following "instructions for caponing chickens"? This choice specimen of the art of causing pain needlessly and with no compensatory purpose is, we are assured, issued by a respectable house of business for the information of its customers. The origin of the "instructions" is said to be American. Further comment is unnecessary:

"Instructions for Caponing Chickens.—The chicken should be about three months old, and kept without food for about thirty-six hours before the operation, which is best performed on an ordinary table, in a good light. Place the fowl on the table on its left side, and tie one end of a string about three feet long to the wings, to secure them, having previously attached a weight to the other end of this string, which must be dropped over the end of the table, so that it will remain suspended; then take the legs of the fowl and attach another string and weight in the same manner, in order that the wings and legs may be secured for the operation, which is performed thus:—Pick the feathers from the hip bone over the last rib; take a sponge and wet the ribs and feathers around, so that they will be out of the way during the operation. Insert

the knife about half an inch between the first and second ribs from the hip-bone, and cut downwards and forwards to the end of the ribs; then turn the knife and cut up near the backbone. Now put in the spreaders and regulate the tension by the india-rubber band to suit the size of the fowl. Open the ribs and cut through the middle membrane that covers the bowels. Take the forceps and grip the upper testicle, and turn the forceps over once, thereby separating the testicle from all its attachments except the spermatic cord; now pull the testicle out. Repeat the operation on the lower testicle. Be careful to remove the whole of the testicles. Also carefully avoid the large vein under the testicles, or the operation might terminate fatally. Now unite and let the bird go. The incision must not be sewn up. The fowl should not be allowed to roost for a few days. If carefully performed, the loss by the operation does not exceed 3 per cent. The practical result of this operation is to largely increase the weight of the fowl."

DANGERS OF INFECTION FROM GLAZED EARTHENWARE.—According to the *Journal du Ceramiste et du Chauffournier*, M. Payrussen has just addressed a note on this subject to the Academy of Sciences, in which he points out the danger of using glazed earthenware in connection with the administering of food to hospital patients. Amongst other causes of danger, reference is made to the quantity of lead contained in the glaze, no less than .22 of a gramme of sulphate of lead having been found to exist in 100 grammes of milk which had fermented in a vessel of the kind indicated. Reference is made to the economical and entirely inoffensive process of M. Constantin, which is a varnishing with boro-silicate of lime, for the adoption of which the intervention of the Government is suggested. The results of experiments made have pointed to the fact that vessels in which broth or milk have once been allowed to ferment afterwards cause that process to ensue more rapidly, even if carefully cleaned.

A TUMOUR OF HAIR REMOVED FROM THE STOMACH OF A YOUNG GIRL BY LAPAROTOMY.—The following case is reported in the *Pester Med. Chir. Presse*. A somewhat anæmic and nervous girl, fifteen years of age, had since her tenth year suffered considerably from chlorotic troubles, which for the last three years were associated with acute indigestion. For the last year and a half an extremely movable tumour was noticed in the abdominal cavity, which was by some taken for a movable kidney, notwithstanding the fact that some of the symptoms were not in accord with this diagnosis. The pains finally became so severe that laparotomy was performed, when the tumour in the stomach was found to be made up of short hairs, mixed with vegetable cells, starch grains, etc. It weighed 283 grm., and was 13½ ctm. long, 10½ ctm. broad, and 5½ ctm. thick. It was compact and superficially very black. The result of the operation was complete relief. The patient acknowledged that for the past four years she had been in the habit of biting off the ends of her hair and swallowing them. The majority of her schoolmates did the same, believing it would give them clear voices. Seven similar cases occur in the literature of the subject, and one case is recorded where a malignant tumour of the stomach and intestines proceeded from this cause.
